## EXECUTIVE SUMMARY

This report provides the results of studies conducted by the Cornell Biological Field Station on Oneida Lake in 2022 and compares these results to previous data collected as part of the longterm monitoring program. Oneida Lake is New York State's $3^{\text {rd }}$ most heavily-fished lake. Walleye Sander vitreus has historically received the majority of angler effort followed by black bass Micropterus spp. Long-term monitoring of the fisheries and limnology of Oneida Lake has captured a series of changes in recent decades that have resulted in pronounced changes in the lake's physical and biological characteristics including reductions in nutrient inputs resulting from the Great Lakes water quality agreements, establishment of invasive dreissenid mussels resulting in increases in water clarity, increases in summer water temperatures and decreases in duration of ice cover, and establishment of a breeding population of double-crested cormorants Phalacrocorax auritus. New arrivals include round goby Neogobius melanostomus, first reported by anglers in 2013 and in standard fisheries surveys in 2014, and spiny water flea Bythotrephes longimanus in 2019. In addition, the burrowing mayfly Hexagenia rigida and H. limbata has returned to the lake. Assessments of the impacts of these additions are ongoing.

Long-term analyses show significant changes in abundance of many important sport and prey fish species. To differentiate long-term from recent changes with more immediate management implications, analyses of fisheries data are focused on the period beginning in 2007. This year was chosen because quagga mussels Dreissena rostriformis bugensis started to increase in the lake at that time. Quagga mussels further increased water clarity and decreased Daphnia spp. abundance, an important food item for age-0 fish. Establishment of a double-crested cormorant population contributed to declines in yellow perch Perca flavescens and walleye populations in the 1990s, but an aggressive management program combined with a period of more restrictive walleye harvest regulations has aided the recovery of these two important fish species.

Walleye adult abundance is currently near average, and the yellow perch adult abundance remains near a record high. Adult walleye growth and condition improved in 2022 after 3 subpar years due to low age-0 yellow perch and gizzard shad Dorosoma cepedianum abundances relative to the size of the walleye population, while adult yellow perch length at age has increased with increases in round goby and burrowing mayfly. The smallmouth bass Micropterus dolomieu population has generated concern in recent years. Lower catches of age-0 fish in several gears and older fish in gill nets are fueling these concerns. Recent smaller year-classes are consistent with the arrival of round goby, which is a known egg and larvae predator. However, age-0 catches of other nesting Centrarchid spp. do not appear to be decreasing. Angler catch rates continue to be characteristic of a very good walleye fishery, as defined by the Walleye Management in New York State plan, as well as a good black bass fishery. The walleye harvest regulation change from 3 fish/day to 5 fish/day instituted on May 1, 2022 contributed to the harvest of over 100,000 walleye.

Oneida Lake continues to support quality sustainable fisheries for walleye, yellow perch and black bass. Continued monitoring of the lake's limnology and fish populations will track the impacts of ongoing ecological changes and guide management directed at sustaining or improving quality recreational fisheries.

## INTRODUCTION

Oneida Lake is the largest lake by area entirely within the borders of New York State (51,000 acres, 20,700 hectares) and is third only to lakes Ontario and Erie in total angling effort in New York State. Duda et al. (2019) estimated 649,000 angler-days/year on Oneida Lake in 2017, compared to 1.5 million angler-days/year on Lake Ontario and 659,000 angler-days/year on Lake Erie. Effort estimates conducted by the Cornell Biological Field Station (CBFS) have produced annual levels of open water effort in excess of 165,000 boat-hours in every year since 2010 (see below). Angling on Oneida Lake generates revenues of over 21 million dollars annually (Duda et al. 2019), and as such represents an important resource both locally and across the state. Traditionally, walleye Sander vitreus has been the primary focus of the Oneida Lake fishery, with yellow perch Perca flavescens and black bass (smallmouth bass Micropterus dolomieu and largemouth bass M. salmoides) also providing popular fisheries.

The Oneida Lake walleye population is intensively managed through annual stockings of walleye fry, management of double-crested cormorants Phalacrocorax auritus, and angling regulations that have been imposed and relaxed with the goals of retaining both a high walleye yield and a yellow perch population capable of providing forage for walleye and other sport fish (Forney 1980). Angling regulations are based on intensive monitoring of the walleye and yellow perch populations and predicted walleye recruitment.

Oneida Lake has been the subject of research by CBFS since its establishment in 1956. Work on Oneida Lake is an important part of the collaboration between Cornell's Department of Natural Resources and the Environment and the New York State Department of Environmental Conservation's Bureau of Fisheries (NYSDEC). Research and monitoring on Oneida Lake are designed to encompass a range of trophic levels, from nutrients to fish and anglers, and these data are used to improve our understanding of the interactions between the ecosystem and the fishery. During the time span that data have been collected, a series of perturbations has resulted in fundamental changes in the lake and how it functions. Events that have resulted in demonstrable impacts on Oneida Lake's dynamics include the Great Lakes Water Quality Agreement of 1972 (with amendments in 1983 and 1987), establishment of a nesting colony of double-crested cormorants in the 1980s, and invasion by zebra mussels Dreissena polymorpha in the early 1990s (followed by the invasion by quagga mussels Dreissena rostriformis bugensis in the mid-2000s). More recent additions to the biotic community include the return of burrowing mayfly Hexagenia spp. in the early 2010s, and the arrival of round goby Neogobius melanostomus in the mid-2010s and spiny water flea Bythotrephes longimanus in 2019. Impacts of these additions are still being assessed.

In this report, we provide analyses that incorporate data during two time periods. We use data from the beginning of the data set to 2022 to assess long-term trends, and data from 2007 to 2022 to assess more recent trends that may have more immediate management implications. The more recent time period spans the years during which zebra mussels were replaced by quagga mussels (Hetherington et al. 2019), with concomitant declines in chlorophyll a and Daphnia spp. biomass (identified with change-point analyses, Jackson et al. 2019), and is characterized by ongoing double-crested cormorant management efforts and consistent walleye harvest regulations until 2022 when the daily bag limit was increased from 3 to 5 fish. This shorter time frame for trend analyses was explored with the intention of allowing detection of responses to recent perturbations free from the influence of more well-established shifts in lake dynamics associated with water quality improvements, increases in the double-crested cormorant population, and the initial colonization of the lake by zebra mussels. With this
approach we hope to separate documented trends that were a result of past changes from those that may suggest a response to new changes (e.g., round goby, burrowing mayfly).

Collection of data to maintain the long-term database and directed studies aimed at understanding the effects of ecosystem change on fish populations were continued in 2022 by the DNRE of Cornell University as part of the activities of CBFS. Funding was provided by NYSDEC through the Federal Aid in Sport Fish Restoration Program and from the CBFS endowment. Appendices that appear at the end of the report describe standardized methods for data collection (Appendix 1) and provide standard data arranged in tables (Appendix 2). Many of our data sets are available for download from the Knowledge Network for Biocomplexity (http://knb.ecoinformatics.org/index.jsp), a data repository that is a member node of the National Science Foundation DataONE portal (www.dataone.org). These data-packages include method descriptions and metadata for limnology, ice data, phytoplankton, zooplankton, benthic invertebrates, mussels, gill-net data, trawl data, walleye, and yellow perch and are described in Rudstam et al. (2016a). They are updated annually and are associated with this report.

## METHODS

Much of the data presented in this report result from continuation of long-term sampling protocols established at the outset of the CBFS studies on Oneida Lake. Detailed methods for both limnological and fisheries surveys can be found in Appendix 1 and in the metadata on the Knowledge Network for Biocomplexity website. Many of the equations that appeared in the text of recent annual reports are now provided in Appendix 1.

## RESULTS

## Limnology

Oneida Lake has a wealth of long-term limnological data including benthic invertebrates (1956present), zooplankton (1964-present) and phytoplankton and nutrients (1975-present). Annual measurements of these lower trophic level parameters (Appendix 2 Table A1) allow for an ecosystem-based approach to understanding fish population dynamics in the lake. Here we report on year 2022 and discuss implications for Oneida Lake. This section also provides analyses of limnological time trends from 1975 to 2022 using standard linear regression (Table 1) and ANOVA (Table 2). New for this section is the addition of mussel biomass to these analyses and inclusion of more information on benthic invertebrates.

Table 1. Analyses of the 1975-2022 long-term trends in limnological indicators using simple linear regression. Trend is the rate of change per year in the units given, SE is the standard error of these trend values, adjusted $r^{2}$ indicates the proportion of the variance explained, N is the number of years included, and the $p$-values represent the statistical significance. Values $\leq 0.05$ are considered significant and in bold. Variables are explained in Table 2. Mussel biomass was analyzed from 1992 to 2022. Analyses were conducted using the statistical package Jmp v16.0.

| Indicator | Trend | SE | adj $r^{2}$ | N | $p$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Summer temp at $6 \mathrm{ft}\left({ }^{\circ} \mathrm{F}\right)$ | 0.10 | 0.014 | 0.9 | 48 | $<0.001$ |
| Ice duration (days) | -0.65 | 0.25 | 0.13 | 47 | 0.008 |
| Summer BDO <3ppm (\%) | 0.53 | 0.14 | 0.23 | 48 | 0.0004 |
| TP $(\mu \mathrm{g} / \mathrm{L})$ | -0.41 | 0.097 | 0.28 | 48 | $<0.0001$ |
| SRP $(\mu \mathrm{g} / \mathrm{L})$ | -0.13 | 0.060 | 0.07 | 47 | 0.037 |
| Chorophll $(\mu \mathrm{L} / \mathrm{L})$ | -0.15 | 0.018 | 0.60 | 48 | $<0.0001$ |
| Secchi $(\mathrm{ft})$ | 0.086 | 0.019 | 0.30 | 48 | $<0.0001$ |

| Mussel biomass $\left(\mathrm{g} / \mathrm{m}^{2}\right)$ | 2.24 | 2.46 | 0.0 | 31 | 0.37 |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Daphnia $(\mu \mathrm{g} / \mathrm{L})$ | -1.65 | 0.34 | 0.33 | 48 | $<0.0001$ |
| Other zooplankton $(\mu \mathrm{g} / \mathrm{L})$ | -0.06 | 0.34 | 0.00 | 48 | 0.86 |

In last year's report (VanDeValk et al. 2022), changes in limnological data were analyzed by comparing four time periods that correspond to major changes in Oneida Lake (Table 2): Eutrophic Period (1975-1986), Pre-Mussel Period (1987-1991), Zebra Mussel Period (19932007) and Quagga Mussel Period (2009-2022). Note that the 2022 values are included in the QM period. Table 2 also provides data for 2022 separately. Although adding one more year to these analyses was not expected to change the conclusions made last year, it is still informative to see how 2022 compares with the observed time trends. The years 1992 and 2008 were excluded from these analyses as those years were considered transition years. Periods were compared using ANOVA followed by Tukey's HSD to test for differences among time periods.

Table 2. Analyses of limnological data divided in four time periods: 1) Eutrophic (1975-1986), 2) Pre-Mussel (1987-1991), 3) Zebra Mussel (ZM, 1993-2007), and 4) Quagga Mussel (QM, 2009-2022). The ANOVA column shows the adjusted $r^{2}$ and in parentheses the number of years and the overall model $p$-value; significant models ( $\mathrm{P}<0.05$ ) are in bold. Other columns provide the average annual values for each time period. Annual values are in Appendix 2 Table A1. Letters indicate significant differences between time periods. Summer temp is the average temperature for June through August at 6.6 ft depth, Ice is number of days with complete ice cover, BDO is the percent of sites sampled in June-August with bottom dissolved oxygen values below 3 ppm, TP (total phosphorus), SRP (soluble reactive phosphorus), Chl (chlorophyll), Secchi (a measure of water clarity), Daphnia spp. (dry mass) and Other zoop (dry mass) are calculated as averages of weekly values from May through October. Mussels refers to both zebra and quagga mussel shell-on dry weight collected in the annual fall survey (September through November). Analyses conducted using the statistical package Jmp v16.0.

| Indicator | ANOVA | Eutrophic | Pre-Mussel | ZM | QM | 2022 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Summer temp ( ${ }^{\circ} \mathrm{F}$ ) | 0.47 (46, <.0001) | 70.0 [A] | 71.2 [A,B] | 72.3 [B,C] | 73.4 [C] | 73.9 |
| Ice (days) | 0.06 (45, 0.13) | 100.5 [A] | 92.8 [A] | 82.7 [A] | 79.6[A] | 71 |
| BDO <3ppm (\%) | 0.14 (46, 0.026 ) | 9.2 [A] | 13.0 [ $\mathrm{A}, \mathrm{B}$ ] | 20.0 [A,B] | 25.8 [B] | 16 |
| TP ( $\mu \mathrm{g} / \mathrm{L}$ ) | 0.56 (46, <0.0001) | 42.5 [A] | 26.3 [B] | 23.3 [B] | 24.8 [B] | 29.1 |
| SRP ( $\mu \mathrm{g} / \mathrm{L}$ ) | 0.30 (45, 0.002) | 15.5 [A] | 8.2 [A, B] | 7.9 [B] | 8.9 [B] | 15.2 |
| Chl ( $\mu \mathrm{g} / \mathrm{L}$ ) | 0.71 (46, <0.0001) | 9.7 [A] | 8.5 [A] | 5.6 [B] | 4.1 [C] | 4.2 |
| Secchi (ft) | 0.51 (46, <0.0001) | 8.5 [A] | 9.2 [A] | 11.8 [B] | 11.8 [B] | 10.2 |
| Mussels ( $\mathrm{g} / \mathrm{m}^{2}$ ) | 0.10 (29, 0.053) |  |  | 289 [A] | 378 [A] | 363 |
| Daphnia ( $\mu \mathrm{g} / \mathrm{L}$ ) | 0.46 (46, <0.0001) | 103 [A] | 82 [A] | 95 [A] | 43 [B] | 15 |
| Other zoop. ( $\mu \mathrm{g} / \mathrm{L}$ ) | $0.0(46,0.457)$ | 132 [A] | 122 [A] | 111 [A] | 120 [A] | 85 |

Several limnological parameters in 2022 mirrored trends identified in last year's report (VanDeValk et al. 2022). Water temperature was again high. The year 2022 had the 6th highest June-August temperature in the data set which was consistent with a trend of $\sim 1^{\circ} \mathrm{F}$ increase per decade observed since 1975 (Figure 1A, Table 1). All five warmer summers have occurred since 2005. For a global perspective that includes Oneida Lake see O'Reilly et al. (2015). Although not yet detrimental to walleye growth, average lake temperature during the warmest months (July-August, $75.9^{\circ} \mathrm{F}$ ) was higher than the optimum temperature for walleye growth ( $73.4^{\circ} \mathrm{F}$, Kitchell et al. 1977, Lantry et al. 2008). Ice duration was relatively short in 2021-22 (Table 1, two weeks shorter than the average since 1975), consistent with the trend since 1975 of shorter ice duration on the lake (Figure 1A). Loss of ice cover is accelerating in lakes worldwide (see Sharma et al. 2021 for an analysis of worldwide trends that includes Oneida Lake). Average May-October water clarity remained high and chlorophyll levels low
(Figure 1B), consistent with the impact of zebra and quagga mussels on the lake (Karatayev et al. 2023). Major algae blooms were not observed in 2022.

Figure 1. Time trends of major limnological measures for Oneida Lake 19752022. Data available in Rudstam (2023a,b), Rudstam and Jackson (2022) and in Appendix 2 Table A1.

Phosphorus levels increased in 2022 compared to the last four years although values were similar to measurements in 2000-2014 (Figure 1C). Higher phosphorus levels occurred particularly in the late summer and fall periods and coincided with low nitrate levels. Although phosphorus limits Oneida Lake algae production in early summer (Volponi et al. 2022), these results suggest that algae were limited by nitrogen and not phosphorus in late summer and fall of 2022. Daphnia spp., a preferred zooplankton prey for young fish, declined to the lowest levels recorded to date in 2022 (Figure 1D). This was likely related to the spiny water flea and to a moderate population of age-0 fish in 2022. Our preliminary analysis suggests the low Daphnia did not negatively impact age-0 yellow perch in 2022, and effects were likely offset by consumption of spiny water fleas (as observed for 2020 and 2021, Jordan et al. 2023). The spiny water flea Bythotrephes longimanus was still abundant in 2022 but less so than in 2020 and 2021. In 2021 this species contributed about half of age-0 yellow perch diets by mass and, contrary to expectations, did not negatively affect age-0 yellow perch growth (Jordan et al. 2023).

Oxygen levels in bottom waters ( $33 \mathrm{ft}[10 \mathrm{~m}$ ] depth) were below 3 ppm (limiting to fish) on 8 of the 50 (16\%) sampling occasions in June through August 2022. This was a lower percentage of days of oxygen depletion than average in the zebra and quagga mussel periods although the overall trend of increasing occurrence of low oxygen in the bottom waters continues (Tables 1 and 2). Hetherington et al. (2015) showed that this trend is expected given increasing temperatures; however, the time between strong wind events may also be important.

The lake-wide decline in zebra and quagga mussel biomass coincident with the arrival of round goby did not continue. The mussel biomass increased in 2021 and 2022 compared to low values in 2020 (Figure 2) due to recruitment of age-0 mussels in both 2021 and 2022. The decrease in quagga mussels from 2017 to 2020 may be attributed to round goby predation (Brooking et al. 2022), but the round goby population remained high in both 2021 and 2022. The increase in mussel biomass occurred primarily on soft substrates while gobies are more abundant on rocky and sandy substrates where mussel biomass remained low.

Figure 2. Dreissenid biomass (SODW is shell on dry weight) in Oneida Lake 1992-2022. Zebra mussel biomass indicated in black, quagga mussel biomass in yellow. Error bars represent 1 SE . Data available online in Rudstam (2023c).

Several benthic invertebrate groups (amphipods, snails, caddisflies, worms), major food resources for yellow perch and white perch Morone americana, have declined with the invasion of the round goby (Brooking et al. 2022), and low densities of these groups continued in 2021 and 2022. However, there was some increase in snails in 2022 compared to 2020 and 2021 (Figure 3).

Figure 3. Trends in benthic invertebrates that have decreased (top panel) and remained the same or increased (bottom panel) since the arrival of zebra mussels, 1993 to 2022. The scale on the $\mathbf{Y}$ axis refers to the proportion of the maximum value recorded in 1993-2022 for each group. Values are averages of spring, summer and fall densities found in two deep and one shallow benthic grab sites. Total numbers of grabs included in each value range from 19 to 42 . Data available online in Rudstam (2023d).

In contrast to these benthic invertebrates, the burrowing mayfly Hexagenia spp., was again abundant in the lake in 2022 (Figure 4) and was a major part of yellow perch and white perch diets, as it has been since about 2012 (Brooking et al. 2022). The burrowing mayfly is likely to affect predator-prey interactions between yellow perch and walleye by buffering predation on age-0 fish by the adults of these species. The presence of abundant mayfly in June may lead to better survival of age-0 year classes of both species.

Figure 4. Changes in Hexagenia spp. abundance in Oneida Lake from the benthos survey (since 2005) and the mussel survey (since 2018). See Hetherington et al. (2019) and Brooking et al. (2022) for details on methods.

Increased consumption of round goby and of burrowing mayfly by yellow perch and white perch compensated for declines in consumption of other benthic invertebrates, and a decline in growth rates of these fish species through 2020 was not detected (Brooking et al. 2022).

Oneida Lake continues to change both physically and biologically. Climate change has resulted in warmer summer water temperatures and shorter duration of ice cover. Warm summer water temperatures may make the lake a better place for warmwater species such as sunfish and bass, but a worse place for walleye and yellow perch. Invasive species that are affecting food web interactions and ecosystem function are zebra mussels (arrived in 1991) quagga mussels (in 2005), round goby (in 2013), and the spiny waterflea (in 2019). Other important changes are the return of the native burrowing mayfly in high numbers since 2019 and declines in other bottom fauna and Daphnia. These physical and biological changes will affect the lake's fish community and its fishery, but note that these changes can be both positive and negative for the fishery.

## Fish Community

The Oneida Lake fish community is sampled using gill-net surveys (since 1957, except 1974) to assess subadult and adult percid abundances, trawl surveys (since 1961) to assess offshore prey fish abundances, seine surveys (intermittently since 1959) and fyke-net surveys (since 2007) to assess inshore prey fish abundances, hydroacoustic surveys (since 1993) to assess pelagic prey fish abundances, spring electrofishing surveys (since 2011) to assess the centrarchid community, and spring (since 1992) and fall (since 1957) trap-net surveys to assess seasonal inshore adult fish abundances. Fish community survey results by gear are provided below.

Gill-net survey - Gill-net catches in Oneida Lake are typically dominated by yellow perch, white perch and walleye. These three species have represented over $70 \%$ of the total gill-net catch in every year since sampling started in 1957. In 2022, the gill-net catch of walleye was 301 fish (Appendix 2 Table A2); below the long-term average of 372 fish but similar to the average catch since 2007 of 336 fish (Figure 5). The gill-net catch of white perch was 351, above the longterm average of 308 fish but lower than the average of 437 fish since 2007. The gill-net catch of yellow perch was 2,279, continuing an increase that started in 2018 and exceeded all other annual catches since the early 1980s. The smallmouth bass catch matched 2019 with a catch of 17; the lowest observed since the mid 1980s. Other common species such as freshwater drum Aplodinotus grunniens, gizzard shad Dorosoma cepedianum and white sucker Catastomus commersonii were captured in numbers within the range of recent years. Notable catches of less common species in the gill net include 15 rock bass Ambloplites rupestris which was the third year in a row with a double digit catch (highest observed since 1989). The pumpkinseed Lepomis gibbosus catch was also relatively high. Burbot Lota lota catches in gill nets since 1957 indicate significant population declines; no burbot were caught in gill-net surveys since 2013. Fall trap-net surveys also indicate a significant decline; the mean catch per net-night in fall trap nets since 2000 was 1.35 burbot, well below the average from previous years (Appendix 2 Table A20, 5.22 fish/net-night, data on file, CBFS).

Figure 5. Total annual catch of three major fish species in standard gill-net surveys in Oneida Lake since 1957. There was no gill-net survey conducted in 1974.

Trawl survey - Seven species of prey fish were caught in standard 18-foot trawl surveys in 2022 (Appendix 2 Table A3). Age-0 yellow perch (106.5/haul) was the most abundant prey fish species, followed by round goby (16.6/haul) and white perch (4.2/haul). Round goby and age-0 walleye, yellow perch, white perch and smallmouth bass trawl catches are discussed further in the Species of Interest section below. For the third year in a row the catch of trout-perch Percopsis omiscomaycus (1.8/haul) was lower than all other years between 1977 and 2019 while the 2022 catch of age-1 and older pumpkinseed (1.3/haul) was the third highest on record (the catch in 2021 being the highest, data on file, CBFS). Otoliths removed from a sample of 27 pumpkinseed indicated a strong 2019 year class ( $74 \%$ of the trawl catch) which was consistent with 32 fish aged from gill nets (66\%). No tessellated darters Etheostoma olmstedi were caught in trawl surveys for the fifth year in a row and only six have been caught in 980 trawl hauls after 2014 when round goby arrived. The mean CPUE prior to 2014 was $8.40 / \mathrm{haul}$. The loss of Etheostoma spp. after round goby arrival has been documented elsewhere (Lauer et al. 2004).

Fyke-net survey -Catches in the large ( $1 / 2 \mathrm{in}$ ) mesh nets in 2022 were dominated by age- 1 and older yellow perch (19.4/net-night) followed by age-1 and older pumpkinseed (6.2/net-night, Appendix 2 Table A4). The age-0 largemouth bass catch fell below 1.0/net-night and the age-0 smallmouth bass catch remained below 1.0/net-night for the third year in a row.

Catches in the $3 / 16$ in mesh nets in 2022 were dominated by age-0 Lepomis spp. (325.4/netnight) followed by age-0 yellow perch (131.6/net-night) and round goby (33.2/net-night, Appendix 2 Table A4). Catch rates of other species were all below $5.0 /$ net-night. The age-0 largemouth bass catch rate fell below 1.0/net-night for the first time since 2017 while the age-0 smallmouth bass catch rate increased from last year to 1.3/net-night (but still below the data set average of 3.3/net-night, Appendix 2 Table A4).

Fyke nets provide the only index of young of year largemouth bass abundance prior to the initiation of regular shoreline seining in 2015, and also show potential as an index for sunfish and esocids. Fyke nets do not show potential as an index of adult black bass, and an index of largemouth bass requires shoreline electrofishing. Fyke nets are one of our primary gear for indexing age-0 smallmouth bass abundance over the long term (beach seining serves as a more traditional index but has not been conducted as consistently since the mid-2000s as fykenet sampling). The use of fyke nets as an index of age-0 black bass abundance is discussed in more detail in the Black bass section of the Species of Interest.

Shoreline seine survey - A shoreline seine survey was implemented in 2015 to address potential shifts in habitat use by age-0 yellow perch from offshore areas (where they are indexed by our trawl samples) to inshore areas (Fetzer 2013, Fetzer et al. 2015). Daytime seining with a $75 \mathrm{ft}(22.9 \mathrm{~m})$ beach seine with $1 / 4$ in mesh is conducted at nine sites with available long-term data once every month from July through September.

Seine samples in 2022 were dominated by age-0 yellow perch (138.3/haul) and round goby 123.7/haul for the three surveys conducted. Banded killifish Fundulus diaphanous (33.4/haul) and emerald shiner Notropis atherinoides (21.2/haul) were the other two most common species caught (Appendix 2 Table A5). Catch rates for all other species were less than 20/haul. The catch/haul of round goby in 2021 and 2022 were the two highest on record.

Centrarchid survey - In spring 2011, a shoreline electrofishing survey directed at centrarchids was initiated. In 2022, age-1 and older largemouth bass were captured at the highest rate among predators, followed by walleye (Figure 6, Appendix 2 Table A6). The smallmouth bass
catch rate remained stable at $2.6 / \mathrm{hr}$ but the chain pickerel catch rate was the lowest on record, continuing the decreasing trend that started in 2017.

Figure 6. Catch rate (\#/hr) of predators in spring electrofishing surveys for Oneida Lake since 2011. Chain pickerel was not included as a target species in 2019.

Hydroacoustic survey - Pelagic prey fish (gizzard shad, emerald shiner and alewife/blueback herring Alosa spp.) abundance and biomass are estimated in the fall using hydroacoustics with supporting small-mesh gill nets and midwater trawling. Total pelagic prey fish density in 2022 was estimated at 531 fish/acre ( 1,312 fish/hectare, long-term average was 4,162 fish/acre, Appendix 2 Table A8). Biomass of pelagic prey fish was estimated at $10.5 \mathrm{lb} /$ acre $(9.4$ $\mathrm{kg} / \mathrm{hectare}$, long-term average $28.5 \mathrm{lb} / \mathrm{acre}$, Appendix 2 Table A8). Age-0 gizzard shad densities were higher than observed the previous 3 years but still only about half the long-term average of 989/acre, and age-0 and adult emerald shiner densities were the lowest since assessments began in 1993 (Figure 7). Biomass of pelagic prey fish was the third lowest on record. The pelagic prey fish survey did not catch any alewife Alosa pseudoharengus or blueback herring $A$. aestivalis. These clupeids were common in early surveys (1993-1996) but have been caught in low numbers in only seven surveys since.

Figure 7. Time trends in biomass (lb/acre) of emerald shiner and age-0 gizzard shad from hydroacoustic estimates for Oneida Lake since 1993.

## Species of Interest

More detailed population assessments of species of particular interest are provided below. These species are walleye, yellow perch, white perch, black bass (smallmouth bass and largemouth bass), lake sturgeon Acipenser fulvescens, round goby and double-crested cormorants.

Walleye - The walleye population in Oneida Lake is assessed at several life stages: as larvae (lengths of $9-13 \mathrm{~mm}$ ) with Miller high-speed samplers; as juveniles in the spring, summer and fall with bottom trawls; and as juveniles and adults with gill nets in the summer. Adult (age-4 and older) abundance estimates are supported with mark-recapture estimates at regular intervals (currently every 3 years).

The 2022 adult walleye population was estimated using mark-recapture. A total of 21,560 age-4 and older walleye ( 10,805 males and 10,755 females) were marked with a left ventral (LV, also called pelvic fin) fin clip from late March through mid-April. Recapture efforts from June into November provided 1,660 adults for examination for clips of which 56 were clipped. The resulting adult walleye abundance was estimated at $628,000( \pm 23 \%$, Figure 8; Appendix 2 Table A9). The 2016 year-class remained strong accounting for almost half of the adult population. The adult walleye population has shown a significant increasing trend since 2007 (Table 3).

Figure 8. Density of adult (age-4 and older) walleye in Oneida Lake since 1957. Red markers indicate mark-recapture years with associated $95 \%$ confidence limits. Secondary y-axis provides population scale.

Table 3. Recent trends (2007-2022) in walleye abundances at various life stages in Oneida Lake. Significance levels are based on simple linear regression. Data are presented in Appendix 2 Table A9. Trend indicates direction (+ or -) over time, with $r^{2}$ and $p$ reported for regressions. Significant trends indicated by bold type.

| Variable | Trend | $r^{2}$ | $p$ |
| :---: | :---: | :---: | :---: |
| Adult population size | $\boldsymbol{+}$ | $\mathbf{0 . 4 7}$ | $<0.01$ |
| Larval density | - | 0.06 | 0.77 |
| Age-0 density | + | 0.05 | 0.42 |
| Spring age-1 density | - | 0.03 | 0.56 |

The catch for the recapture portion of the mark-recapture was obtained by pooling catches from multiple offshore and inshore sampling methods. Offshore areas were surveyed using gill nets and bottom trawls (18' trawl prey fish surveys and 30/40' trawl surveys conducted specifically for mark-recapture). Inshore areas were surveyed using fyke nets and electrofishing (spring Centrarchid survey in June and fall electrofishing surveys conducted specifically for markrecapture). Most (70\%) of the catch examined for clips came from fall targeted electrofishing surveys, followed by targeted 30/40' trawl surveys (15\%) and gill net surveys (9\%) with the remaining 3 surveys accounting for $5 \%$ of the fish examined combined. Estimates of the lakewide adult walleye population derived using offshore catches only can be substantially different than estimates using inshore catches only. Of the 29 walleye mark-recapture estimates generated since 1957, only 12 comparisons between estimates based on offshore catches and estimates based on inshore catches from the same year differed by $30 \%$ or less, with estimates based on offshore catches being higher $83 \%$ of the time. In 2022, the estimate based on offshore catches was $32 \%$ higher than the inshore estimate and CLs did overlap.

The discrepancy between estimates based on offshore and inshore catches could be due to the distribution of sampling effort. One of the assumptions of mark-recapture is that marked fish randomly mix with unmarked fish OR that recapture effort is distributed in proportion to the number of fish in different parts of the population area (Van Den Avyle 1993). Walleye marked at the hatchery do not randomly mix with the unmarked population (Forney 1963); therefore, offshore and inshore recapture effort is distributed in proportion to fish density. However, because recapture effort of gears used offshore is not comparable to effort of gears used inshore, it is unclear whether fish are sampled in proportion to their offshore and inshore abundances. In 2005, walleye caught by electrofishing during the fall recapture period were marked with a unique fin clip. Walleye were subsequently examined the following spring (2006) for fall 2005 clips. The resulting fall estimate from fall tagging was in close agreement with the previous spring's estimate. However, the 1,276 walleye marked in the fall provided only 14 recaptures the following spring resulting in wide $95 \%$ CLs. While this exercise did provide some reassurance that our recapture methodology was valid, continued discrepancy between estimates from offshore and inshore catches is concerning. Year 2 of the scheduled telemetry project should provide valuable insight into the post-spawn distribution of walleye clipped at the hatchery for mark-recapture population estimation.

The adult population estimated by age provided an observed mortality of $84 \%$ over the 3 -year period (2019-2022). The resulting annual mortality rate for that period was 0.46 , more than triple what was estimated from 2016-2019 (0.14). Two possible explanations for the dramatic increase in mortality are: 1) angler harvest increased substantially during the period from 20192022 , or 2 ) the 2019 adult population was over-estimated, or a combination of the two. While angler harvest can result in high annual mortality (for example anglers removed $50 \%$ of the adult population in 1959, Grosslein 1961) estimates of harvest in 2019 and 2021 were approximately $10 \%$ annually. Angler harvest in 2020 was not estimated due to covid but the harvest rate required to account for the observed 3 -year mortality rate of $84 \%$ would have had to have been around $70 \%$ which is unlikely. The 2019 adult walleye population estimate was based on only 24 recaptures and resulted in a $95 \%$ CL of $33 \%$. If we assume the 2019 population was actually at the lower end of the $95 \%$ CL ( 700,000 , still within the $95 \% \mathrm{CL}$ ) the resulting 2016-2019 mortality rate increases to 0.24 and the 2019-2022 mortality rate decreases to 0.38 . At this lower 2019 population level a harvest rate of 0.40 in 2020 would account for the remainder of the mortality from 2019 to 2022.

Average catches of age-1 and age-2 walleye in trawls and gill nets combined with gear-specific catchabilities derived by Irwin et al. (2008) are used to predict future recruitment at age-4 (Jackson et al. 2020). Based on these relationships, we predict the 2019 year-class will add 90,000 age-4 fish to the adult stock in 2023 and the 2020 year class to add 133,000 age-4 fish in 2024. These additions combined with the 2022 mark-recapture estimate of adults (adjusted for annual mortality-25\%, Irwin et al. 2008) suggest the adult population should remain at about 600,000 fish through 2024.

Adult walleye length at age is determined from fish collected in fall (typically October) using 40-ft bottom trawls and electrofishing. Despite significant increases in growth from 2007 through 2019 (Jackson et al. 2020), recent poor growth (Figure 9) has resulted in no change in length at age over the period of 2007-2022 (linear regression: age-4: $\mathrm{N}=16 ; r^{2}=0.07 ; p=0.93$; age-5: $\mathrm{N}=16 ; r^{2}=0.07 ; p=0.82$; age-6: $\mathrm{N}=16 ; r^{2}=0.01 ; p=0.70$ ).

Figure 9. Observed length at age for ages 4-6 walleye from fall trawls and electrofishing for Oneida Lake since 1960.

Because observed length at age is a culmination of growth conditions of every year the fish is alive, relative weight is likely a better indicator of growth conditions for a particular year. Fall relative weight is used to monitor condition of age-1 and older walleye caught in 40 -ft trawl and electrofishing surveys each year (Figure 10). Relative weights for 2020 and 2021 were among the lowest in the data set. However, relative weight in 2022 exhibited a modest recovery ( 2022 $\mathrm{W}_{\mathrm{r}}=90$ ) approaching the long-term mean (mean $\mathrm{W}_{\mathrm{r}}=94$, since 1963).

Figure 10. Relative weight $\left(W_{r}\right)$ of age-1 and older walleye caught in fall trawl and electrofishing surveys for Oneida Lake since 1963.

Recent decreases in length at age and condition are indicative of a changing predator-prey community. Walleye growth has historically been dependent on availability of young yellow perch, with gizzard shad and white perch providing additional forage in recent decades (VanDeValk et al. 2008). Round goby was added to the forage base in 2014. Decreases in growth and condition observed in 2020 and 2021 are likely due to lower prey fish densities per walleye (Appendix 2 Tables A3 and A8). Fall diet assessments are consistent with these observations. The number of fish per pound of walleye examined in those years were below the long-term (since 1971) average, and gizzard shad, which typically are the most abundant diet item in the fall, appeared in fall diets at a lower rate than any year since 2003 (Appendix 2 Table A10). The modest recovery in length at age and condition observed in 2022 was likely due to a combination of fewer adult walleye and an increase in prey fish abundance. The recent addition of round goby to the Oneida Lake prey fish community has not resulted in improved growth of adult walleye to date despite being numerically the first or second most common fall diet item in recent years.

The Oneida Fish Cultural Station (OFCS) stocked 168 million walleye fry in Oneida Lake from late April to May 2 in 2022. The estimated larval abundance approximately 2.5 weeks after stocking was 339 fish/acre ( 838 fish/hectare, Figure 11) about half the long-term mean (648 fish/acre). To date no relationship between larval density and density at any later life stage has been demonstrated (Rudstam et al. 2016b).

Figure 11. Time trends in larval walleye density (\#/acre) for Oneida Lake for various years since 1966. Red markers indicate larval density estimates for years no walleye fry were stocked.

Data sets of fall age-0 and age-4 abundances indicate that the 2022 walleye year class may contribute substantially to the adult stock in 2026 despite low abundance at the larval stage. Age-0 walleye are monitored with 18 -ft bottom trawl surveys beginning in mid to late July and catch per unit effort (CPUE) is converted to density assuming that each trawl samples an area of 0.25 acre ( 0.1 hectare) and there is no avoidance by young fish. Age- 0 walleye densities and mean lengths on October 1 are from trawl surveys surrounding October 1 (approx. 9/15 to $10 / 15$ ). This year the October 1 age-0 walleye density estimate was 8.1 fish/acre ( 20.0 fish/hectare, Appendix 2 Table A11). This fall age-0 density was the highest observed since 1991 (Figure 12, Appendix 2 Table A11). Fall age-0 density is positively correlated with
abundance at age-4 (Rudstam et al. 2016b). Additionally, the mean length on October 1 was 7.4 in (189 mm), the highest observed since 1998 (Appendix 2, Table A11). Forney (1976) found that the relative survival of walleye between the first and second year of life was 0.84 and 0.82 for the 1971 and 1973 year classes (mean length in October was 6.8 in and 6.7 in) compared to 0.006 to 0.19 for other year classes from 1966-1973 (mean lengths averaged 5.05.7 in ). The combination of a relatively high fall age-0 density and large size going into the winter suggests we can expect a significant contribution from the 2022 walleye year class to the adult stock in 2026.

Figure 12. Time trends in density (\#/acre) of age-0 walleye on October 1 based on bottom trawls for Oneida Lake since 1961.

As early as 2014 we hypothesized the addition of round goby to the Oneida Lake prey base may increase growth and decrease mortality of young walleyes (Jackson et al. 2015). Age-0 walleye mortality in Oneida Lake is attributed to predation by older walleyes, and predation is influenced by abundance of alternate prey as well as growth of young walleyes as it affects cannibalism (Forney 1976). Young walleye growth is determined by temperature and the abundance of appropriate-size prey fish (Forney 1966). The round goby spawns multiple times in a season so their addition to the fish community should provide appropriate-size prey for age0 walleye throughout the season. Diets of age-0 walleye caught in 12-15 trawl surveys from July-October have been examined each year since 1961 (Figure 13). Diets over this 61-year period reflect the transition from a prey fish community dominated by age-0 yellow perch during the 1960s into the early 1980s to later-spawning species (including darter sp., white perch, sunfish, and gizzard shad, Hall and Rudstam 1999) during the mid-1980s through the early 2010s to round goby since 2014. While variable, length attained by October has not exhibited a trend despite the changes in the prey fish community (Figure 14). While it would have been convenient to attribute the large size of this year's age-0 walleye to round goby availability as we had hypothesized, age-0 yellow perch clearly were responsible for providing the energy to young walleye for growth as they accounted for $79 \%$ of all species identified in young walleye stomachs with round goby (14\%), age-0 gizzard shad (4\%), Lepomis spp. (2\%) and logperch Percina caprodes (1\%) accounting for the remaining 21\%. Eleven mayflies (Hexagenia spp.) were recorded from the 179 stomachs examined.

Figure 13. Species composition of fish identified in diets of age-0 walleye caught in trawls since 1961.

Figure 14. Mean length of age-0 walleye caught in trawls in October since 1961.
The shift in 2022 to yellow perch dominating young walleye diets is not easily explained. Age-0 yellow perch were sampled at the $18-\mathrm{mm}$ stage (see below) from June 13-15 (mean date June 14, 3 days later than the long-term mean date) and were found to be relatively abundant (nearly twice the mean since 2007, see Figure 18 below). Age-0 yellow perch abundance was again sampled using trawls when they averaged 1.0 g in weight. In 2022, the date yellow perch averaged 1.0 g was July 25, the latest since 1994 (9 days later than the mean) so early-life growth was relatively slow. By August 1 age-0 yellow perch density was half the average observed since 2007. Age-0 walleye averaged 4.8 in ( 123 mm ) by the time trawl surveys commenced in late July, by far the largest for recent years examined (since 1998, Figure 15). It appears age-0 walleye established a growth advantage over age-0 yellow perch shortly after the
yellow perch larval survey that allowed utilization of age-0 yellow perch as prey throughout the summer, an advantage not observed since the early 1980s. Analyses of factors affecting firstyear walleye growth and survival are ongoing.

Figure 15. Mean length of age-0 walleye at first trawl survey (late July) since 1998.
The adult walleye population in Oneida Lake declined through the 1990s presumably due to double-crested cormorant predation on subadult fish (Rudstam et al. 2004). Aggressive doublecrested cormorant management combined with a more restrictive daily harvest limit of three fish and 18 in minimum length contributed to a steady recovery through the 2000s and 2010s (Figure 8, Appendix 2 Table A9). After record high adult populations of around 1 million fish in 2019 and 2020, increased adult mortality and relatively low recruitment have resulted in a return of the adult population to slightly above the long-term average of 600,000 fish. Observed adult mortality combined with expected recruitment suggest the adult population will remain near the current level for the next 2 years.

Yellow perch - The yellow perch population in Oneida Lake is assessed at several life stages: as larvae with Miller high-speed samplers; as juveniles in the spring, summer and fall with bottom trawls and seines (summer and fall age-0 only); and as adults (age-3 and older) with gill nets in the summer.

In 2022, the method used to estimate the adult yellow perch population was modified in order to be more consistent with estimates provided on-line and used in recent publications. The new method still bases population estimates on gill-net catches but the catches are corrected for gill net selectivity by age rather than mean length (for a more detailed description of yellow perch abundance estimation see Appendix 1 Gill-net surveys). Estimates derived from the two methods are closely related ( $\mathrm{N}=62, r^{2}=0.97, p<0.001$ ). The population estimate of adult yellow perch in 2022 was 3.0 million (58.2/acre, 144/hectare) and was the highest since 1981 (Figure 16, Appendix 2 Table A12). Catches over the last five summers reflect a recovery from a population low observed in 2014. The adult yellow perch population has increased significantly since 2007 (Table 4).

Table 4. Recent trends (2007-2022) in adult and first-year yellow perch populations for Oneida Lake. Significance levels are based on simple linear regression. Data are presented in Appendix

2 Tables A12 and A13. Trend indicates direction (=, + or -) over time, with $r^{2}$ and $p$ reported for regressions. Significant trends indicated by bold type.

| Variable | Trend | $r^{2}$ | $p$ |
| :---: | :---: | :---: | :---: |
| Adult population size | $\mathbf{+}$ | $\mathbf{0 . 4 9}$ | $<0.01$ |
| Larval density | - | 0.03 | 0.53 |
| Age-0 density | - | 0.16 | 0.13 |
| Sge-0 mean length | + | 0.08 | 0.30 |
| Spring age-1 density | - | 0.01 | 0.83 |
| Summer age-1 density | + | 0.11 | 0.23 |

Figure 16. Time trends in age-3 and older yellow perch densities (\#/acre) for Oneida Lake since 1961.

The catch in gill nets is also used to estimate age-2 yellow perch abundance (Figure 17, Appendix 2 Table A12) and year class abundance at age-2 is closely related to abundance the following year when they recruit to the adult population at age-3 ( $N=64 ; r^{2}=0.79 ; p<0.001$ ). The age-2 gill-net catch in 2022 was higher than any year except 1979 suggesting this year class (2020) could contribute substantially to an already high adult population in 2023. The 1977 year class of yellow perch was by far the strongest year class of yellow perch observed since monitoring began in the late 1950's and nearly quadrupled the adult population in 1980 by adding almost 4 million age-3 fish. Unlike the 1977 year class, the strength of the 2020 year class was not evident in trawl catches at age-0 or age-1 (see below). Reasons for this remain unclear. Catches of age-0 yellow perch in fyke-net surveys did indicate a strong 2020 year class but seine surveys did not.

Figure 17. Time trends in age-2 yellow perch densities (\#/acre) for Oneida Lake since 1961.
Abundance of age-0 yellow perch is measured at the larval stage (two surveys: 8 mm and 18 mm ), and in 18 -ft bottom trawls through the summer, and again as yearlings in trawls centered on May 1 (Appendix 2 Table A13). The larval yellow perch density at the 18 mm stage in 2022 was 40,200 /acre ( 99,400 /hectare) which was higher than the long-term average of 27,200 /acre ( $67,000 /$ hectare), and the highest since 2010 (Figure 18). Fall density of age-0 yellow perch was 334/acre (825/hectare, average of October trawl surveys) in 2022, below the long-term average of 385 /acre ( $950 /$ hectare, Figure 18). Spring yearling catches of yellow perch from the 2021 year-class indicated a density of 7.7/acre (19/hectare, Figure 19).

Figure 18. Time trends in larval and fall age-0 yellow perch densities (\#/acre) for Oneida Lake since 1961.

Figure 19. Time trends in spring and summer age-1 yellow perch densities (\#/acre) for Oneida Lake since 1962. The 1977 year-class spring yearling density was $1,370 /$ acre.

While recent abundances of adult yellow perch have reached 30-year highs, larval densities, fall age-0 densities and summer catches of age-1 fish all exhibited significant declines over the long term (Irwin et al. 2009; Rudstam et al. 2016b). The last decade has shown some moderation of the declining trends in subadult abundances observed over the long term, with no significant trends in abundance for first-year life stages since 2007 (Table 4). Yellow perch still represent the primary forage for adult walleye prior to gizzard shad recruiting to their diets in late summer and fall. As a result, mortality of age-0 yellow perch remains high, but survival of subadults after their first year must be high to allow for the observed increase in the adult population. Reduced predation by double-crested cormorants, which was once the bottleneck for young percid recruitment, is likely contributing to increased subadult survival.

White perch - Based on gill-net catches, the white perch population in Oneida Lake increased sharply through the late 1990s and 2000s (Figure 20) exceeding gill-net catches of yellow perch in 2007, 2009-2011, and 2015 (Appendix 2 Table A2). Recruitment is variable, but the white perch recruitment index was suggestive of successful ( $\mathrm{Rl}>200$ ) year-classes at least once every 3 years from the mid-1990s through 2004. However, only two relatively large year-classes have been observed since 2005 (Appendix 2 Table A14). Infrequent strong year classes in recent years have resulted in a significant decline in adult catches in gill nets since 2007 (linear regression: $\mathrm{N}=16 ; r^{2}=0.36 ; p=0.01$ ). White perch diets are similar to yellow perch, although they appear to feed more on larval and juvenile fish. The decline in adult numbers likely contributed to recent increases in survival of larval percids (Jackson et al. 2020). For a more thorough assessment of white perch recruitment in Oneida Lake see VanDeValk et al. 2016.

Figure 20. Time trends in annual gill-net catches of white perch for Oneida Lake since 1961. No gill-net surveys were conducted in 1974.

Black bass - Black bass are an important sport fish in Oneida Lake. Opening of a spring catch-and-release fishery in 2007 was met with some concern about potential impacts on young of year bass production, but early studies of potential impacts of spring fishing showed catches of age-0 smallmouth bass over the first 6 years following the opening of spring fishing were significantly higher than those from the 6 years preceding the regulation change (Jackson et al. 2015). However, age-0 smallmouth bass abundance now appears to be decreasing, while age0 largemouth bass abundance has not changed significantly. All four age-0 smallmouth bass indices we currently incorporate into our annual sampling ( $18-\mathrm{ft}$ trawl, shoreline seine, small mesh fyke nets and large mesh fyke nets) indicate significant decreasing trends in age-0 abundance since 2007 (Table 5). Catches of age-0 smallmouth bass in seines, 18 -ft trawls, and small-mesh fyke nets were correlated (Table 6). Jackson et al. (2015) reported trawl catches of young of year smallmouth bass year-classes were significantly correlated with later gill-net catches at age-4 and age-5 (1984-2007 year-classes). A similar analysis using data for the 2007-2016 year-classes and all four age-0 indices indicated none of the age-0 indices were correlated with adult abundance (VanDeValk et al. 2022). Age-0 largemouth bass abundances showed no significant trends in any of the three indices (shoreline seine, small mesh fyke nets and large mesh fyke nets) since 2007 (Table 5). For age-0 largemouth bass, only catches in the two fyke nets were correlated [Corr. Coefficient=0.68 ( $p=0.008$ )].

Table 5. Recent trends (2007-2022) in measurements of age-0 smallmouth bass and largemouth bass abundances from various gear for Oneida Lake. Smallmouth bass data were log transformed $\left[\log _{10}(C P U E+0.1)\right]$, largemouth bass data were normally distributed. Significance levels are based on simple linear regression. Data are presented in Appendix 2 Tables A3-5. Trend indicates direction (+ or -) over time, with $r^{2}$ and $p$ reported for regressions. Significant trends indicated by bold type.

| Species | Variable | Trend | $r^{2}$ | $p$ |
| :---: | :---: | :---: | :---: | :---: |
| Smallmouth | 18 -foot trawl | - | $\mathbf{0 . 5 1}$ | $\mathbf{0 . 0 0 2}$ |

| bass | Shoreline seine | - | 0.53 | $\mathbf{0 . 0 0 5}$ |
| :---: | :---: | :---: | :---: | :---: |
|  | Fyke net (small mesh) | - | $\mathbf{0 . 4 5}$ | $\mathbf{0 . 0 0 7}$ |
|  | Fyke net (large mesh) | - | $\mathbf{0 . 2 5}$ | $\mathbf{0 . 0 5}$ |
| Largemouth | Shoreline seine | - | 0.21 | 0.11 |
| bass | Fyke net (small mesh) | + | 0.03 | 0.57 |
|  | Fyke net (large mesh) | + | 0.01 | 0.97 |

Table 6. Spearman rank correlation analysis comparing age-0 smallmouth bass catches from four gear from 2007-2022. Table provides correlation coefficient ( $p$-value). Values in bold indicate significant correlation.

|  | 18 -ft trawl | Seine | Small-mesh fyke |
| :---: | :---: | :---: | :---: |
| Seine | $\mathbf{0 . 8 5 ( 0 . 0 0 0 3 )}$ |  |  |
| Small-mesh fyke | $\mathbf{0 . 8 1 ( 0 . 0 0 0 2 )}$ | $\mathbf{0 . 7 8 ( 0 . 0 0 3 )}$ |  |
| Large-mesh fyke | $0.35(0.19)$ | $0.50(0.09)$ | $0.46(0.08)$ |

Catches of age-1 and older smallmouth bass in standard gill nets have decreased significantly since 2007 (Table 7) and are now in the range observed during the 1970s and early 1980s (Figure 21). Electrofishing CPUE since 2011 did not reveal any significant trends for smallmouth bass or largemouth bass (Table 7).

Table 7. Recent trends in catches of age-1 and older smallmouth bass in gill-net surveys (20072022) and age-1 and older smallmouth bass and largemouth bass in shoreline electrofishing surveys (2011-2022) for Oneida Lake. Significance levels are based on simple linear regression. Data are presented in Appendix 2 Tables A2 and A6. Trend indicates direction (+ or -) over time, with $r^{2}$ and $p$ reported for regressions. Significant trends indicated by bold type.

| Species | Variable | Trend | $r^{2}$ | $p$ |
| :---: | :---: | :---: | :---: | :---: |
| Smallmouth bass | Gill net | - | $\mathbf{0 . 3 5}$ | $\mathbf{0 . 0 2}$ |
| Largemouth bass | Electrofishing | - | 0.18 | 0.23 |
|  | Electrofishing | + | 0.01 | 0.83 |

Figure 21. Time trends of age-1 and older smallmouth bass catches in gill-net surveys for Oneida Lake since 1957.

Age structure of smallmouth bass captured in spring electrofishing surveys and gill-net surveys confirm suggestions of variable recruitment (Table 8). Catches of older (age-7 and older) smallmouth bass that declined after the mortality event initially reported in the fall of 2017 have increased.

Table 8. Percent composition by age of smallmouth bass collected in spring electrofishing surveys and gill-net surveys in Oneida Lake since 2011. Ages are from scales for electrofishing surveys and from otoliths for gill-net surveys. Note smallmouth bass are not fully recruited to gill nets until age-3.

| Year | N | Age-1 | Age-2 | Age-3 | Age-4 | Age-5 | Age-6 | Age-7 | Age>7 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  | Electrofishing survey |  |  |  |  |  |  |
| 2011 | 30 | 36.7 | 16.7 | 3.3 | 10.0 | 6.7 | 6.7 | 6.7 | 13.3 |
| 2012 | 49 | 14.3 | 30.6 | 14.3 | 8.2 | 8.2 | 6.1 | 10.8 | 8.1 |
| 2014 | 44 | 2.3 | 22.7 | 29.5 | 4.5 | 20.3 | 6.8 | 20.5 | 11.3 |

| 2021 | 36 | 5.6 | 27.8 | 27.8 | 8.3 | 16.7 | 5.6 | 0 | 8.3 |
| 2022 | 17 | 0 | 11.8 | 29.4 | 23.5 | 11.8 | 5.9 | 5.9 | 11.8 |

Age structure of largemouth bass captured in spring electrofishing samples confirms suggestions of variable recruitment indicated by size structure analyses (Table 9). Catches in 2019 indicated small 2017 and 2018 year classes, both consistent with age-0 fyke-net samples. The strong 2019 year class was reflected in catches at age-1, age-2 and age-3, also consistent with age-0 fyke-net samples. Spring electrofishing is currently our only index of age-1 and older largemouth bass abundance.

Table 9. Percent composition by age of largemouth bass collected in spring electrofishing surveys in Oneida Lake since 2011.

| Year | N | Age-1 | Age-2 | Age-3 | Age-4 | Age-5 | Age-6 | Age-7 | Age>7 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 2011 | 83 | 7.2 | 6.0 | 14.5 | 15.7 | 9.6 | 18.1 | 16.9 | 12.0 |
| 2012 | 113 | 8.8 | 13.3 | 20.4 | 11.5 | 6.2 | 10.6 | 8.0 | 21.3 |
| 2014 | 105 | 1.9 | 16.2 | 28.6 | 10.5 | 8.6 | 5.7 | 11.4 | 17.3 |
| 2015 | 76 | 0.0 | 0.0 | 9.2 | 18.4 | 22.4 | 5.3 | 3.9 | 40.8 |
| 2017 | 100 | 24.0 | 13.0 | 27.0 | 1.0 | 4.0 | 12.0 | 7.0 | 12.0 |

| 2019 | 60 | 0.0 | 8.3 | 26.7 | 31.7 | 15.0 | 6.7 | 5.0 | 6.7 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 2020 | 113 | 27.4 | 11.5 | 8.8 | 11.5 | 12.4 | 11.5 | 8.0 | 8.8 |
| 2021 | 75 | 4.0 | 22.7 | 30.7 | 10.7 | 9.3 | 13.3 | 4.0 | 5.3 |
| 2022 | 129 | 0 | 16.3 | 43.4 | 12.4 | 5.4 | 10.1 | 6.2 | 6.2 |

To date, scales were the structure of choice for aging largemouth bass because collection is non-lethal (Besler 1999). However, scales are unreliable due to the difficulty in distinguishing annuli with increasing age and decreasing growth (Beamish and McFarlane 1987). Unlike scales, the annuli in otoliths continue to be discernable during periods of minimal growth (Marshall and Parker 1982, Beamish and McFarlane 1987). In 2022, otoliths were collected in addition to scales from 57 largemouth bass caught in electrofishing surveys. Ages determined from scales and from otoliths were in agreement for $25 \%$ of all fish aged, and for $29 \%$ of fish age-7 or less. Ages were within $+/-1$ year for $84 \%$ of all fish aged, and $90 \%$ for fish under age8. Ages determined from scales were higher for $77 \%$ of age-2 and age-3 fish, and by as much as 2 years, resulting in significantly lower length at age for those ages (Figure 22). The maximum age from scales was age-10, whereas otoliths indicated $9 \%$ ( 5 fish) were older than age-10, with one fish estimated at age-16.

Figure 22. Length at age for largemouth bass determined by scales and by otoliths (error bars provide $90 \% \mathrm{Cls}$ ).

A similar comparison of ages determined from scales and from otoliths was conducted for smallmouth bass caught in gill-net surveys in 2021 and 2022 (Figure 23). Ages were in agreement for $74 \%$ of all fish aged, and were within $+/-1$ year for $94 \% ~(N=53)$. Ages determined from scales were higher for $21 \%$ of young (ages $1-3$ ) fish but not by more than 1 year, and were lower for $33 \%$ of older (age-4 and older) fish by 1 to 5 years. Mean lengths calculated by the two aging structures were not statistically different for any age.

Figure 23. Length at age for smallmouth bass using scales versus otoliths (error bars provide 90\% Cls).

The status of the smallmouth bass population is now an issue of concern. Recent decreases in adult indices combined with relatively poor young abundances suggest the population will not recover to levels observed from the late 1980s to early 2010s any time soon. Reasons for these decreases remain unclear but the timing is consistent with the establishment of a round goby population. Young and adult abundances will continue to be monitored closely in an attempt to identify factors contributing to these decreases. There is no indication that the adult largemouth bass population has changed significantly since monitoring began in 2011.

Lake sturgeon - Lake sturgeon catches from directed sampling with large mesh gill nets in 2022 were within the range observed since surveys started in 2002 (Figure 24; Appendix 2 Table A15). Fourteen lake sturgeon were caught in the 6-12 in mesh panels in 2022, with the 14 in panels contributing an additional two fish. Lake sturgeon stocking was terminated in 2004 but began again in 2014 with the stocking of 500 fish (stocking at that level has continued annually since). To date, catches since stocking was resumed have shown a significant increasing trend but only marginally ( $6-12$ in mesh only, simple linear regression: $N=8, r^{2}=0.28, p=0.09$ ). This trend should strengthen as stocking continues and if natural reproduction increasingly contributes to the population. Catch records now include evidence of successful natural reproduction and survival of young from 10 year-classes between 2011 and 2020 (none from 2018). Twenty-five fish were either aged to years that lake sturgeon were not stocked or were untagged and aged to years that all stocked fish were tagged. Likely spawning locations include Fish Creek (spawning activity reported by anglers) and other tributaries to the lake.

Figure 24. Time trends in spring large mesh gill-net catches of lake sturgeon for Oneida Lake since 2002. Note 14 in mesh panels were added to the gill-net gang in 2019.

Round goby - Round goby first appeared in CBFS trawl surveys in 2014 and has since been caught in other sampling gear. While several standard gears used in our sampling capture round goby, the catches in these gear show considerable annual variability that do not correlate well among gear. The use of videos to assess round goby abundance has become increasingly popular (Schaner et al. 2009) and has been found to be the best technique for assessing round goby size and density across a wide range of substrates (Johnson et al. 2005; Andres et al. 2020). In 2018 an annual lake-wide video survey that samples depths and substrates in proportion to their availability was initiated. Video surveys in 2018 and 2019 were comprised of 97 sites, but the survey has since been reduced to a more efficient 46 sites in a random stratified design that is conducted in early July.

The round goby population has increased since the die off in 2016. Round goby density estimates from video surveys were 16,000/acre (39,700/hectare) in 2021 and 16,700/acre ( $41,200 /$ hectare) in 2022, up from a low of 1,700/acre (4,100/hectare) in 2018 (Figure 25). Low catches of round goby early in 2017, combined with reports and direct observations of concentrations of dead round gobies along shore prior to ice on suggested a die off in the winter of 2016-2017. There has been no evidence of die offs in other winters, so it is uncertain if the 2016-2017 die off was an isolated event related to disease or some other factor.

Figure 25. Relative abundance of round goby (seine and trawl) since 2014 and densities from video surveys since 2018. Error bars represent $90 \%$ confidence limits.

It is uncertain as to what round goby densities we can expect for Oneida Lake because studies that provide density estimates in other systems are few and estimates generated from video surveys need to be assessed for round goby attraction/avoidance to the video apparatus. Karatayev et al. (2021) estimated the round goby density in the 33 to 115 ft depth range of Lake Ontario at 17,000 fish/acre. Taraborelli et al. (2009) estimated round goby densities as high as $15,702 /$ acre in the shallowest areas of the lower Bay of Quinte 6 years after round goby invasion. Andres et al. (2020) estimated the round goby density for main portion of Cayuga Lake shallower than 60 ft at 7,365/acre with lower densities in the vegetated north end 6 years after invasion. This year's lake-wide video estimate of 16,700 fish/acre for Oneida Lake 8 years after invasion approaches the highest observed in the literature. However, potential attraction/avoidance to the video apparatus has not been accounted for by most of these studies including ours. Andres et al. (2020) found that a camera mount with a larger on-bottom foot print than our camera stand increased the effective area sampled due to attraction by a factor of four in Cayuga Lake, New York.

Establishment of a round goby population appears to be having mixed effects on other biota in Oneida Lake. Since their arrival, round gobies have been utilized as a prey resource for piscivores. Yellow perch and white perch appear to be taking advantage of their arrival most with round gobies occurring in $8.3 \%$ of diets of each species examined from gill nets, followed by smallmouth bass ( $7.4 \%$ ) and walleye ( $5.7 \%$ ). Since the arrival of the round goby and the reappearance of the burrowing mayfly, mean lengths of age-0 smallmouth bass as well as adult yellow perch and white perch have increased significantly (Brooking et al. 2022). In Lake Erie, round gobies were detected in the diets of all piscivorous species examined, but significant increases in growth were only documented for smallmouth bass, yellow perch and burbot (Steinhart et al. 2004; Johnson et al. 2005). Analyses indicate round goby is having a negative impact on benthic invertebrate densities (Brooking et al. 2022). Continued sampling should allow detection of any responses in terms of fish diets and growth. We should be wellpositioned to detect any longer-term changes in the limnology of the lake and its fish community
given that both pelagic and littoral sampling have been underway for some time in advance of the arrival of round goby.

Double-crested cormorants - Since the early 2000s the double-crested cormorant population on Oneida Lake has been managed to varying degrees by USDA Wildlife Services and then NYSDEC. For a more detailed description of the double-crested cormorant management history on Oneida Lake see Coleman et al. (2016). Management since 2010 has been conducted by NYSDEC and was focused initially on efforts to push migrants off the lake because summer numbers of resident double-crested cormorants remained low and there were no observed nesting attempts. In 2013, summer counts and nesting efforts exhibited increases and NYSDEC began implementing a full season hazing program in 2014 with a target goal of no more than 100 double-crested cormorants on the lake and no successful nesting. Management efforts have had a direct effect on the number of feeding days by double-crested cormorants on Oneida Lake (Figure 26).

Figure 26. Total annual feeding days of double-crested cormorants on Oneida Lake since 1978. Feeding days calculated from weekly bird counts conducted by USDA Wildlife Services (20042009) and NYSDEC personnel.

Diets were examined from 192 birds in 2022. A total of 967 prey items were identified (Appendix 2 Table A16). The most common prey items numerically were round goby (75\%) followed by yellow perch (10\%) and gizzard shad (8\%). No other species accounted for more than $3 \%$ of observed diets. Gizzard shad, which was typically the most common species found in fall diets, fell from an average of 4.7/bird (2004-2019) to $0.08,0.19$ and 0.47 per bird from 2020 to 2022, respectively. By weight, yellow perch made up 38\% of double-crested cormorant diets, walleye $22 \%$, round goby $16 \%$ and gizzard shad $13 \%$, with no other species accounting for more than 6\%. Analyses of double-crested cormorant diets over a 20-year span found positive selection for schooling, soft-bodied prey such as gizzard shad when they were
available, so buffering of potential impacts on percids by fall migrating double-crested cormorants was realized in years when gizzard shad were abundant in the fall (DeBruyne et al. 2013). But gizzard shad fall densities have been low since 2019 (see Hydroacoustic survey, above) so species other than gizzard shad were consumed to meet metabolic requirements, mainly yellow perch and walleye. In the absence of gizzard shad, consumption of percids by double-crested cormorants can be substantial. To date, round goby has been a minor contributor to double-crested cormorant diets accounting for an average of 15\% (range: 5-32\% since 2015) of the total biomass of fish consumed. But evidence from other systems suggests that round goby can dominate double-crested cormorant diets (Johnson et al. 2010) which could happen in Oneida Lake if round goby becomes more abundant especially in larger length classes.

## Creel survey

The current approach for monitoring angler effort and success on Oneida Lake is to conduct an abbreviated summer creel survey each year, basing effort on boat counts from May, June and July and basing catch and harvest rates on exit interviews conducted at public boat ramps during June and July. The abbreviated summer survey is complemented by a full (summer and winter) roving survey every fifth year (2022-23). Estimates of angler effort and success in 202223 focus on the full roving survey as it provides data spanning the entire fishing season and likely better represents the Oneida Lake angling population. Exit surveys sample angling parties that utilize public boat ramps only and do not sample lakeside resident angling parties or angling parties that utilize marinas or private boat ramps.

Open water angler effort in 2022 (201,000 boat-h) was similar to the average observed since 2010 (203,000 boat-h, Figure 27, Appendix 2 Table A17). As with most years, effort increased from May to June, peaking in July and then decreasing through the remainder of the open water season. Angling parties that included walleye as a target species accounted for $71 \%$ of all trips and angling parties that included bass as a target accounted for $15 \%$ of all trips. Angling parties interviewed at access points included walleye as a target species on $56 \%$ of all trips and bass as a target species on $38 \%$ of all trips.

Figure 27. Oneida Lake open water (May-September) angler effort (boat-h) since 2010.

Estimated catch rate for walleye (all trips) from 1,419 roving surveys during the 2022 open water season averaged $0.42 / \mathrm{hr}$ (Appendix 2 Table A18), and the mean targeted catch rate was $0.55 / \mathrm{hr}$. The targeted catch rate for walleye was above the average for the period 2012-2021 ( $0.41 / \mathrm{hr}$, Figure 28). Festa et al. (1987) suggested that walleye catch rates of $0.10-0.25 / \mathrm{hr}$ were characteristic of good to very good fisheries, with catch rates exceeding $0.25 / \mathrm{hr}$ considered excellent. For targeted trips, catch rates exceeding $0.20 / \mathrm{hr}$ were above average and rates approaching $0.50 / \mathrm{hr}$ were considered excellent. The walleye harvest rate (all trips) was 0.26/angler-h, the highest observed since 2010 (mean=0.15/angler-h). Smallmouth bass catch rate (all trips) averaged $0.09 / \mathrm{hr}$ and the mean targeted catch rate was $0.52 / \mathrm{hr}$. The targeted catch rate for smallmouth bass was within the range observed during the current survey period.

Figure 28. Targeted angler catch rates for walleye and smallmouth bass for Oneida Lake since 2012. No angler data was collected in 2020.

Historically, the Oneida Lake black bass fishery was dominated by smallmouth bass. Creel surveys in the late 1950's indicated largemouth bass comprised less than 5\% of the total black bass catch reported by anglers (Grosslein 1958). An angler diary program from 1994-98 and a full creel survey in 1997 indicated largemouth bass still accounted for less than $5 \%$ of the black bass catch. However, the contribution of largemouth bass in the total black bass catch started to increase in the early 2000s. Full creel surveys conducted from 2002-2007 indicated largemouth bass comprised between 10 and 19\% (mean=14\%) of the black bass catch. More recently, the contribution of largemouth bass estimated from abbreviated surveys conducted from 2011-2022 increased further to between 18 and $39 \%$ (mean=28\%). It is unclear whether this increase is due to a largemouth bass population that is increasing in response to warmer water temperatures and expanding macrophyte coverage or due to more anglers targeting largemouth bass specifically.

In 2022, angling parties interviewed in roving and exit surveys were asked to specify which black bass species they were targeting. Prior to 2022, target species entries were not differentiated between black bass species. Both survey methods resulted in 5 potential responses: black bass only, black bass in addition to other species, smallmouth bass only, smallmouth bass in addition to other species, and largemouth bass only (Table 10). Both survey methods indicated anglers targeting only largemouth bass accounted for less than $5 \%$ of total black bass effort. Future creel surveys will continue to differentiate between the targeted black bass species.

Table 10. Percent of angling parties targeting black bass by category.

| Target species | Boat ramp surveys | Roving surveys |
| :---: | :---: | :---: |
| Black bass only | 0.51 | 0.11 |
| Black bass and other species | 0.06 | 0.03 |
| Smallmouth bass only | 0.37 | 0.84 |
| Smallmouth bass and other species | 0.03 | 0.01 |
| Largemouth bass only | 0.04 | 0.01 |

Estimated total harvest of walleye for the 2022 open water season was 107,200 fish (Figure 29). With the exceptions of this year and 1959 when over 400,000 walleye were harvested, the open water walleye harvest did not exceed 60,000 fish during years creel surveys were conducted. Total open water harvest of yellow perch was estimated at 145,000.

Figure 29. Open water walleye harvest for Oneida Lake since 2011. No angler data was collected in 2020.

The creel limit for walleye increased from 3 to 5 fish/day on May 1, 2022. Because roving surveys intercept anglers as they are fishing, few ( $0.5 \%$ ) angling parties reported harvesting a 5 fish/angler limit. Under the 3 fish/angler limit, 145 angling parties (10.2\%) would have reported harvesting 3 or more walleye/angler ( $4.3 \%$ reported a harvest greater than 3 fish/angler).

Roving interviews indicated that 85 (4\%) of the 2,142 walleye harvested were caught after a 3fish bag was attained. By applying this rate to the total harvest, 4,280 additional walleye were harvested due to the daily limit increase. A similar analysis using data from exit interviews in June and July indicated 56 angling parties (9.7\%) reported harvesting 3 or more walleye/angler (7.3\% reported a harvest greater than 3 fish/angler and 3.5\% reported a 5 fish/angler limit). Twelve percent of the 781 harvested walleye reported by exit interviews were caught after the 3fish bag was attained.

The 2022-23 winter season was dominated by abnormally poor ice conditions. Ice cover recorded at CBFS resulted in only 13 days of complete ice cover, by far the lowest since the 2001-02 winter of no complete ice cover. Unsafe main-lake ice conditions restricted 2022-23 ice fishing to the bays, and also required modification of the planned creel survey methodology. The creel survey was designed so that the creel clerk traveled the lake by snowmobile to conduct both angler counts and angler interviews. Unsafe ice conditions required the clerk to conduct counts and interviews from 13 access areas located around the lake.

Poor 2022-23 ice conditions likely resulted in relatively low angler effort. Angler counts were conducted from mid-January through early March. Angler effort for the season was estimated at 57,400 angler-h, with $81 \%$ of the effort taking place in February. Comparatively, angler effort estimated for the 2018-19 winter season was 190,300 angler-h.

A total of 197 angler interviews were conducted from mid-January through February. January interviews were dominated by angling parties in Big Bay (56\%) but dropped to 28\% in February as safe ice formed in other bays around the lake. Anglers targeted panfish (including yellow perch) on almost all trips in January with few anglers targeting walleye (14\%). As anglers expanded into other bays around the lake in February, anglers targeted yellow perch on $71 \%$ of all trips, followed by walleye (54\%) and sunfish (28\%). Targeted angler catch rates for the season were 0.23/angler-h for walleye, 1.46/angler-h for yellow perch and 2.75/angler-h for sunfish. A total of 58,000 yellow perch were harvested, followed by 52,100 sunfish and 4,600 walleye.

Angler opinion and behavior survey - As a complement to the catch data collected from angler interviews, we added additional survey questions in 2013 directed at assessing angler opinions about the quality of the Oneida Lake fishery and its management as well as angler activities in areas of recent or current management concern. Four questions were developed with NYSDEC staff and incorporated into angler interviews, 2 of which were new in 2022. Some questions were designed to allow tracking of opinions over time, and some questions were replaced with others, depending on developing issues related to the fishery.

Question 1. On a scale of 1 to 5 , with 5 being very satisfied, how satisfied are you with the overall quality of fishing on Oneida Lake?

From 2013 through 2015, anglers indicated a high level of satisfaction with the quality of angling on Oneida Lake with average scores of 4 or higher. Satisfaction scores fell to 3.2 in 2016, but rebounded to 3.7-4.1 in 2017-2022.

Question 2. Are you aware that the daily limit regulation for walleye on Oneida Lake increased from 3 fish/day to 5 fish/day on May 1 of this year?

Ninety-seven percent of the angling parties interviewed said they were aware of the angling regulation change.

Question 3. Do you think that the current number of bass fishing tournaments on Oneida Lake is acceptable?

Of the 1,419 angling parties interviewed during the roving survey, 571 (40\%) did not think the number of bass tournaments on Oneida Lake was acceptable. Of these parties, 3 thought there were not enough bass tournaments on the lake while the remaining 568 thought there were too many tournaments. A total of 317 parties provided 1 or more reasons they believed there were too many tournaments.

Reasons for too many tournaments:
Anticipated

1. Fish caught too many times/too much fishing pressure 39
2. Fish don't survive 54
3. Fish get relocated 6
4. Launches/lake too crowded 163

Unanticipated
5. Bass anglers are inconsiderate/rude 170
6. Should not fish bass that are guarding nests 9

Question 4. On a scale of 1 to 5 , with 5 being very satisfied, how satisfied are you with the job the NYSDEC Bureau of Fisheries does managing Oneida Lake?

Anglers indicated a high level of satisfaction with NYSDEC's management of Oneida Lake in 2022. The average satisfaction score was 4.5 out of 5 , which was the highest score since adding this question to the survey in 2013. The lowest score was 3.8 in 2018.

## DISCUSSION

Over the duration of our research on Oneida Lake, several ecological changes, some ongoing, have been identified that have affected, or are likely to affect, the fish community. These have included warming water temperatures, species invasions, and increased water clarity resulting from dreissenid mussels and reduced nutrient inputs. The data collected in 2022 are consistent with previous indications that the lake has undergone changes in physical characteristics and productivity at the lower trophic levels. Water temperatures and ice duration continued to reflect warmer conditions than when studies were first initiated, and water clarity remained well above levels observed in the earliest years of our studies. Oneida Lake presently fits the overall characteristics of a mesotrophic system with reduced primary production from the early decades of studies when the lake was classified as eutrophic. Some of the productivity has shifted from the pelagic to the littoral zones including increases in littoral macrophytes and benthic algae production (Cacela et al. 2008) with concomitant increases in abundance of nearshore fish species. There is now evidence of reduced Daphnia spp. production, a typical response to dreissenid colonization, but one that did not occur with only zebra mussels present. The arrival of spiny water flea has exacerbated this decrease. Continued declines in Daphnia spp. densities and conversion of the zooplankton community to one dominated by copepods may have implications for planktivores and planktivorous life stages of important sport fishes.

The current adult walleye population is estimated at 630,000 fish, a decrease from what was observed the previous 4 years but slightly higher than the long-term average $(600,000)$. Accompanying this decrease were increases in condition and growth. Projected recruitment should maintain the adult population at about current levels in the near future. Yellow perch recruitment appears to have increased elevating the adult population to historic highs. Low winter exploitation due to the abnormally short 2022-23 ice season, and projected recruitment of the 2020 year class will likely increase the adult population further in 2023. The presence of round goby and burrowing mayfly may be aiding percid early life survival. Both are available in the spring and early summer at the time when piscivores would otherwise feed on young of year fish. The round goby spawns multiple times in a growing season and young round gobies are providing a valuable food source for young piscivores although increased first-year growth has been documented for smallmouth bass only. Increased first-year growth of fishes has been related to increased over-winter survival (Forney 1976, Irwin et al. 2009). There is evidence that young percid densities are in part limited both through competition with white perch and through direct predation on percid fry by white perch; therefore, it is possible that historic increases in the white perch population may have acted as a constraint on the size of the adult percid populations. Consistently poor white perch year-classes in recent years have resulted in a return of the white perch adult population to levels closer to the 20 year average.

The past decade has seen age-1 and older smallmouth bass numbers decline from the highs observed from the late 1980s through 2012, and production of young smallmouth bass has been low the past 4 years. Based on record catches of young smallmouth bass in fyke nets in 2015 and of largemouth bass young in 2016, there were no early indications of a detrimental impact of round goby on production of young bass. However, the round goby is a known predator of bass eggs and larvae so their effects need to be monitored and reassessed. Bacterial lesions observed in 2017 and 2018 may have affected smallmouth bass, but few have been observed on age- 1 and older fish since.

Round goby is now established in the lake and is affecting the lake's fish populations. Adult yellow perch and white perch growth has increased in the presence of round goby and burrowing mayfly (Brooking et al. 2022). Age-0 smallmouth bass growth has also increased in the presence of round goby. To date, there has been no observed change in age-0 walleye fall length despite round goby accounting for on average $50 \%$ of all the prey fish identified in age-0 walleye stomachs. The round goby population may also buffer sport fish populations from double-crested cormorant predation. Continuing analysis and monitoring of the Oneida Lake data set should provide information on the response to these ongoing ecological changes that are relevant not only to Oneida Lake but also other systems experiencing these changes.

Double-crested cormorant predation on subadult percids resulted in decreases in recruitment to the fishery, but the establishment of a management program contributed to subsequent increases in adult walleye numbers and more recently adult yellow perch numbers. Hazing efforts by NYSDEC personnel continue to keep predation pressure by double-crested cormorants at levels that are well below those observed prior to any management being implemented, especially during the summer months. However, high fall migrant numbers have resulted from cessation of management of populations further north and are increasing impacts on young percids, especially in years when gizzard shad densities are low. In the absence of gizzard shad, percids accounted for $74 \%$ of the fish by weight in double-crested cormorant diets in both 2020 and 2021 and $60 \%$ in 2022. Evidence from other systems suggests that round goby can dominate double-crested cormorant diets (Johnson et al. 2010). Round goby was for the first time in 2016 numerically more common in double-crested cormorant diets than any other species. Round goby was the most commonly consumed species numerically again in

2022 but accounted for less than $20 \%$ of fish in diets by weight. Round goby may provide a buffer for sport fish species against double-crested cormorant predation in Oneida Lake in the future but densities and size may need to increase for that to happen.

Oneida Lake offers diverse, high quality sportfishing opportunities and should continue to do so into the foreseeable future, but recent poor year classes of smallmouth bass will likely have an effect on angler catch rates for that species. Angler catch rates of walleye and smallmouth bass in Oneida Lake have been as dependent on prey abundance as sport fish abundance (Forney 1961; VanDeValk et al. 2005). Moderating predator abundances may increase the likelihood of higher prey fish abundances and lower angler catch rates.

## RECOMMENDATIONS FOR MANAGEMENT AND FUTURE RESEARCH

Fisheries management on Oneida Lake includes stocking of walleye larvae, size and creel limits for walleyes, black bass and other species, and control of double-crested cormorants.

Stocking of walleye larvae. Continue stocking at current levels. Our best estimates suggest that the number of naturally produced walleye larvae in the lake is about $20 \%$ of the numbers stocked (Rudstam et al. 2016b). However in 2020, a year with no fry stocking, the larval walleye abundance estimate was similar to the long-term average. Consequently, stocking walleye larvae in Oneida Lake should be re-evaluated.

Size and creel limits. We recommend maintaining the current size and creel limits for walleye, black bass and other species. Data from the 2022 creel survey indicate that the increase from 3 to 5 fish/angler resulted in an increase in harvest of only $5 \%$ so this regulation change should have little impact on an adult walleye population that is currently near the long-term average.

Double-crested cormorant control. We recommend maintaining current hazing efforts. We have observed an increase in walleye and yellow perch populations concomitant with more intensive double-crested cormorant control. This suggests that removing double-crested cormorants does increase percid recruitment to the fishery. Our data show that a rebuilding of summer double-crested cormorant numbers will likely reduce subadult walleye and yellow perch survival, and potentially reduce populations to the point where recent harvest rates are not sustainable (DeBruyne et al. 2013, Coleman et al. 2016). Current hazing efforts should prevent the rebuilding of a large summer population and minimize fall migrant numbers.

Given the results and discussion in this report, we recommend the following research and monitoring activities in 2023:

1) Continue standard sampling program. This program includes limnological surveys, two larval fish sampling surveys ( 8 and 18 mm yellow perch surveys), 15 standard gill nets, spring weekly trawl surveys from mid-July through October, monthly seine surveys from July through September, video assessment of round goby in early summer, pelagic prey fish survey with acoustics, midwater trawl and pelagic gill nets at the end of August, fyke-net sampling for nearshore fish in September, fall trawling and electrofishing to monitor age-1 and older walleye diet and condition, and large mesh gill nets for lake sturgeon monitoring.
2) Continue the spring Centrarchid survey, and conduct an additional fall Centrarchid survey in in 2023 and 2024 to determine if a fall survey is better suited for black bass population assessment in Oneida Lake.
3) Conduct an analysis of the 3 nearshore fish community assessment gears (seine, fyke net, and electrofishing) to determine if 1 or 2 of the methods can be eliminated from the standard sampling program due to data redundancy.
4) Continue diet analyses of double-crested cormorants in coordination with NYSDEC. Diet information is critical to assessing double-crested cormorant impacts annually.
5) Conduct a creel survey at launch sites in June and July. This low-cost creel survey provides data that is comparable to a full survey and provides information on angling success and impacts useful for management of the resource.
6) Initiate an acoustic telemetry study on adult walleye. This study will ultimately provide a more comprehensive understanding of walleye spawning locations and their relative use in and around Oneida Lake. This study will also describe seasonal walleye movements and habitat use, as well as post-spawn distributions of the Scriba Creek spawning population.
7) Collect both otoliths and scales from largemouth bass caught in 2023 centrarchid surveys. While method consistency is critical when comparing data among years, misrepresentation of growth during early years can lead to misguided management actions. If the discrepancy persists for another year, consider otoliths for largemouth bass aging moving forward.

## Appendix 1: Data collection methods

Limnology. Zooplankton samples are collected weekly (May-October) from 1-4 sites with a 153 $\mu \mathrm{m}$ mesh nylon net ( 1.6 ft , 0.5 m diameter) using a vertical tow from $1.6 \mathrm{ft}(0.5 \mathrm{~m})$ above the bottom to the water surface. Samples are preserved in $70 \%$ ethyl alcohol. Zooplankton are identified, counted, and measured (to the nearest $\mu \mathrm{m}$ ) using a digitizing tablet and microscope. Mean May-October biomass is calculated from weekly averages using the length - dry weight regressions in Watkins et al. (2011). Integrated water samples for total phosphorous (TP) and soluble reactive phosphorous (SRP) are collected using a 7.5 in ( 1.9 cm ) inside diameter Nalgene tube lowered to a depth of $3.3 \mathrm{ft}(1 \mathrm{~m})$ above bottom, and frozen for later analysis. For chlorophyll-a measurements, lake water (up to 2.0 L ) is filtered through Whatman 934-AH glass fiber filters and the filters are frozen for later analysis. Annual averages are calculated as the average of weekly values collected at one to four stations from May to October. All four stations are included when available, except for Secchi depth from the shallow station (Three Mile Bay) because the Secchi disk is sometimes observed on the bottom. Beginning in 2010, one of the original five sites (Buoy 117) was dropped from standard sampling and a new sampling protocol for water chemistry was developed. Four sites were sampled each week, and on Week 1 water samples from each station were processed. On Weeks 2-4, water from all four sites was pooled for analysis. This rotation was maintained throughout the sampling season. Samples were pooled for water chemistry only, not zooplankton. Nutrient samples were analyzed at the Upstate Freshwater Institute (UFI). This EPA approved laboratory uses SM 18-20 4500-P E for TP and SRP, and SM $204500-\mathrm{SiO} 2 \mathrm{C}$ for SRS (APHA 1998). Beginning in 2013, chlorophyll a was analyzed with a Turner Design fluorometer after acetone extraction following the EPA standard operating procedure LG405 with the exception that all samples are run during the winter after the completion of the field season (EPA 2013). A description of the historical methods used prior to 2010 are in the metadata available on the web (www.knb.org).

Larval fish surveys: Miller high-speed sampler surveys are designed to estimate abundance of larval walleye and yellow perch. Larval walleye and yellow perch are sampled when yellow perch reach approximately 8 mm and again at approximately 18 mm . For each survey, the lake is divided into two or more horizontal and vertical depth strata and samples taken at a total of 46 randomly selected sites within designated strata. At each site, four Miller samplers are towed simultaneously at different depths and catches are pooled by stratum. Beginning in 2021, distance towed is measured using GPS and is about one mile ( 1.6 km ) at a speed of 8 mph ( 13 $\mathrm{kph})$. Larval fish captured are identified, counted, and measured. Density estimates are calculated for each strata based on catch and volume of water strained. Catches of yellow perch in the 18 mm survey are adjusted for size-specific gear avoidance (Noble 1970).

For early years when larval walleye densities were estimated from the 9 mm walleye survey, walleye densities were adjusted based on a subset of years when both the 9 mm walleye survey and the 8 mm yellow perch survey were conducted. In years when both surveys were conducted, the larval walleye estimates from the two surveys were correlated ( $r^{2}=0.58, p=$ $0.01, \mathrm{~N}=10$ ). With one outlier removed (2002, when few stocked walleye larvae survived a cold period after stocking), the correlation improves ( $r^{2}=0.88, p=0.0002, \mathrm{~N}=9$ ). The equation is:
$W D_{Y p}=203.6+0.722 W_{9 m m}$
where $W D_{\text {YP }}$ is walleye density at the 8 mm yellow perch survey and $W_{9 m m}$ is walleye density at the 9 mm survey, both in fish/ha.

Gill-net surveys: Standard gill-net catches provide an index of the adult walleye and yellow perch populations as well as relative abundance estimates of various other species. A variable mesh multifilament gill net is fished overnight at a different standard site each week for 15 consecutive weeks starting in the beginning of June and continuing through mid-September. The net consists of four gangs $150 \mathrm{ft}(45.75 \mathrm{~m})$ long by $6 \mathrm{ft}(1.83 \mathrm{~m})$ deep sewn together to form one $600 \mathrm{ft}(183 \mathrm{~m})$ long net. Each gang consists of six $25 \mathrm{ft}(7.6 \mathrm{~m})$ panels with $1.5 \mathrm{in}(38 \mathrm{~mm})$, $2.0 \mathrm{in}(51 \mathrm{~mm}), 2.5 \mathrm{in}(64 \mathrm{~mm}), 3.0 \mathrm{in}(76 \mathrm{~mm}), 3.5 \mathrm{in}(89 \mathrm{~mm})$ and $4.0 \mathrm{in}(102 \mathrm{~mm})$ stretch mesh. The net is set around sunset, fished on the bottom, and retrieved in the morning at about 0730. The time fished varies somewhat with season but has been identical for each location each year. All fish (or a subsample of at least 60 individuals of a species) are measured (total length), weighed, sexed, stomach contents recorded, and scales taken. Large mesh gill nets were used to monitor lake sturgeon reproductive status and abundance and growth in four different substrate types. Nets comprised of two $37.5 \mathrm{ft}(11.4 \mathrm{~m})$ panels of 6 in ( 152 mm ), 8 in ( 203 mm ), 10 in ( 254 mm ), and 12 in ( 305 mm ) stretch mesh monofilament gill nets [total net length $300 \mathrm{ft}(91 \mathrm{~m})$ ] were set for approximately 4 hours at 12 sites monthly in May and June. In 2019 two panels of 14 in ( 356 mm ) were added to the gang. All sturgeon caught were examined for tags, measured, weighed, a fin ray section removed for age determination, diet recorded using gastric lavage, tagged with both a Carlin dangler tag and PIT tag, and released.

Abundance estimates for age-2 and older yellow perch are based on gillnet catches corrected for gill net selectivity by age to be consistent over years except for 1974 (see below). The corrected gill net catch (GNCC) is based on back-casted likely population size given the average annual mortality of $33 \%$ obtained from catch curves for ages 5 to 7 and observed catches. The corrections are based on relative selectivity of the mesh sizes and time of sampling used for the 15 standard sets. With these data, we calculated relative selectivities of 0.203 for Age 2, 0.499 for Age 3, 0.727 for Age 4, 0.934 for Age 5, 1 for Age 6, 0.934 for Age 7 and 0.372 for Age 8 and older. These values are similar to estimates of selectivity based on marked fish and based on girth/length indirect estimates of gill net selectivity of yellow perch in Oneida Lake (Rudstam et al. 2016). The total abundance of age-3 and older fish for a given year is first calculated based on the relationship of GNCC (summed for Age 3 and older) and mark-recapture estimates (MR, in fish/ha) with a 0 intercept (the intercept was not significantly different from 0 ):
$\mathrm{MR}=0.0627(\mathrm{SE} 0.0054)$ * $\mathrm{GNCC}, \mathrm{R}$-squared $=0.70, \mathrm{P}<0.001, \mathrm{~N}=11$
Age specific abundance is calculated based on corrected age specific gill net catches for each year and the total population obtained from this equation. Because this is derived from markrecapture estimates representing April populations, the adult population estimate represents April abundance. Note that this equation is specific for Oneida Lake gill net sampling design.

We chose to base the data series on gill net catches to be consistent across time, and because mark-recapture estimates sometimes were based on limited number of recaptures causing the confidence limits to be large. Catches of adult yellow perch in trawls were not significantly correlated with mark-recapture estimates and were therefore not used. Abundance of different age groups are based on the age structure of the fish caught in the standard gill nets. Gillnets were not used in 1974, for that year the estimate is based on the 1973 and 1975 mark-recapture estimates assuming constant mortality from 1973 to 1975.

Trawl surveys: The catch in trawls provides an estimate of year-class abundance for young-ofyear (age-0) and yearling walleye as well as prey species, primarily young yellow perch.

Trawling begins around the middle of July when age-0 yellow perch become demersal (at about 1 g in weight) and weekly surveys continue until three October surveys are completed. An 18 ft ( 5.5 m ) otter trawl is towed for 5 minutes, sampling approximately 0.25 acre ( 0.10 hectare) per haul. Ten standard sites are sampled in each survey. Age-0 fish are identified, counted, total weight by species recorded, and a subsample of fish measured for length. Lengths are recorded and scale samples taken on all older fish. Regression analysis of catches and lengths (log-transformed) of age-0 walleye and age-0 yellow perch versus date is used to estimate density and mean length by species on September 1 and October 15. If a regression is not significant at the $p=0.05$ level, the mean of the 3 October surveys is used for analyses. A series of three trawl surveys at the same sites centered around May 1 is also conducted to assess age- 1 walleye and yellow perch abundance.

We predict future walleye recruitment using the average of catches in trawls and gill nets of age1 and age-2 walleye. We estimate density of age-1 to 3 walleye from the average of the estimates from the trawl and the gill net using the age- and gear-specific catchabilities derived by Irwin et al. (2008) and predict future recruitment using the catchability-adjusted catches of age-1 and age-2 walleye. The "best" model (determined using the Akaike Information Criterion) given the data for year-classes 1957-2004 includes the natural logarithm of age-1 and age-2 walleye abundance:
$\operatorname{Ln}($ Age-4) $=-0.059+0.239 \operatorname{Ln}($ Age-1 $)+0.593 \operatorname{Ln}($ Age-2 $)$
where Age-1, Age-2 and Age-4 are densities of walleye age classes in fish/ha.
Hydroacoustic surveys: Pelagic fish biomass is estimated around September 1 using hydroacoustics. Surveys are conducted using a 123 kHz split beam unit (Biosonics DT-X, pulse length $0.4 \mathrm{~ms}, 7.8^{\circ}$ beam width) along a set of eight transects from the east to the west ends of the lake. Surveys are typically conducted during two consecutive nights starting one half hour after sunset. Acoustic data are analyzed with EchoView (v6.1 in 2020-21). Echograms are checked for problems associated with poor bottom detection, bubbles from waves, echoes from macrophytes, and other sources of noise. Questionable areas are removed from the analysis. Attempts are made to sample as close to the bottom as possible by re-defining the bottom at high magnification when needed. All densities are calculated from in situ backscattering cross section (average for targets larger than -60dB) and echo integration according to the standard operating procedure for Great Lakes acoustics (Parker-Stetter et al. 2009). Analyses are conducted using each transect as a sampling unit.

Fish are sampled in association with acoustic surveys using a midwater fry trawl and fine mesh gill nets. These gears are used to assess the species composition of young fish in the pelagic zone. The trawl measures $6 \mathrm{ft}(2 \mathrm{~m}) \times 6 \mathrm{ft}(2 \mathrm{~m})$ at the mouth and is mounted in a metal frame. The first 6 ft of the net is comprised of $0.5 \mathrm{in}(12.7 \mathrm{~mm})$ stretch mesh, the next 6 ft of $0.25 \mathrm{in}(6.4$ mm ) stretch mesh, and the cod end of the net consists of a $1.6 \mathrm{ft}(0.5 \mathrm{~m})$ plankton net and bucket with $0.04 \mathrm{in}(1 \mathrm{~mm})$ mesh. At each site, one haul divided into 2.5 minutes at 4.3 to 20 ft $(6.1 \mathrm{~m})$ depth and 2.5 minutes at $6.6 \mathrm{ft}(2 \mathrm{~m})$ to $12.5 \mathrm{ft}(3.8 \mathrm{~m})$ depth (determined from rope angles) and a second 5 -minute haul at the surface (sampling the top $6 \mathrm{ft}(2 \mathrm{~m})$ of the water column) are conducted. Two trawl hauls are completed at each of 10 sites, and fish are preserved in formalin and returned to the lab for species identification, enumeration, and measurement. Fine mesh gill nets, $70 \mathrm{ft}(21 \mathrm{~m})$ long, are set either on bottom or suspended from the surface. Each gill net consists of seven $10 \mathrm{ft}(3 \mathrm{~m})$ wide by $20 \mathrm{ft}(6 \mathrm{~m})$ deep panels of different mesh sizes ( $0.25,0.3,0.4,0.5,0.6,0.7$, and 1.0 in (6.2, 8.0, 10.0, 12.5, 15.0, 18.7 and 25.0 mm ) bar mesh). Paired ( 1 surface and 1 bottom) gill nets are set at each of 4 deep
stations, and 4 shallow stations are sampled with only 1 net that samples the entire water column.

Acoustic density estimates are apportioned to emerald shiners, gizzard shad, and other fish based on catches in vertical gill nets and midwater trawls after accounting for the relative length selectivity and effort of the two gears. Fish in the top $6 \mathrm{ft}(2 \mathrm{~m})$ of the water column that are not surveyed with acoustics are accounted for by calculating the proportion of gizzard shad and emerald shiners caught in the top 6 ft in vertical gillnets set compared to the rest of the water column.

Video survey for round goby: An annual video survey is conducted each year to provide quantitative estimates of round goby. An underwater camera is mounted on a raised frame to count the number of round gobies in a known area of lake bottom. A GoPro Hero 4 or Hero 5 camera is used to record a video at each site. Camera settings are critical for achieving sufficient contrast and light in deeper areas of the lake. The settings used are 2.7 k resolution, $60 \mathrm{f} / \mathrm{s}$ frame rate, and 6400 ISO sensitivity setting. Videos are recorded for 7.5 minutes at each site. It is often necessary to download the camera files onto a laptop or portable drive in the boat as the camera internal hard drive reaches capacity.

The camera is mounted on a black $1 / 2$ " tubular PVC frame with 4 legs designed for the camera face to be $2.0 \mathrm{ft}(0.60 \mathrm{~m})$ from the bottom facing straight down (Figure 1). The viewing area is $5.8 \mathrm{ft}^{2}\left(0.54 \mathrm{~m}^{2}\right)$. A measuring bar of $1 / 4^{\prime \prime}$ metal was placed on the bottom of one leg in the field of view and marked every 0.8 in ( 20 mm ) to allow for estimation of fish length.

Figure 1. Frame used to mount down-looking camera for round goby video surveys.
Forty-six standard sites are sampled over 3-5 days during the first two weeks of July each year (Figure 2). Sites were randomly chosen a priori and were stratified, both spatially and by bottom substrate. Bottom substrate was stratified based on the map by Greeson (1971) with the following number of randomly stratified sites in each bottom type: cobble-16, gravel-7, sand-6, and mud/silt/clay-17. Actual depth was recorded from the boat depth finder.

Figure 2. Map of Oneida Lake showing standard 46 round goby video survey sites.
Windy days or large precipitation events (especially near tributaries) should be avoided as they impair water visibility. The boat is maneuvered to each site location and anchoring is not necessary. The camera recording is started, and the camera frame is lowered on a rope attached to a buoy, with the boat allowed to float away from the site so as not to disturb fish. A timer is used to measure 7.5 minutes from the time the camera reaches bottom. The boat then returns to the site to retrieve the buoy, rope, and camera. The camera recording is stopped upon retrieval.

Recorded videos are analyzed later by projection onto a large computer screen. A screenshot still-frame from each video is saved at the 4,5,6, and 7-minute marks. Round gobies are counted at each interval and averaged to calculate the mean count for each site. The video footage is used to assist identification of round gobies using motion, as they are often difficult to detect from the still frame image. Only fish that are at least $50 \%$ in the viewing frame at the specified time interval are counted. It is often helpful to use a drawing program to circle each fish on the still-frame as it is identified.

Mean round goby counts at each site are divided by the viewing area to calculate the density at each site. Lake-wide density is estimated separately for the hard substrates and soft substrates ( 23 sites each). Average density ( $\# / \mathrm{tt}^{2}$ ) is multiplied by 43,560 to convert to acres, then by the lake area in each substrate class [Hard - 7,366 acres ( $2,981 \mathrm{ha}$ ), Soft $-43,784$ acres (17,719 ha)] to get a lake-wide round goby population in each substrate class. The two estimates are added to provide the final population estimate and confidence limits calculated based on standard sampling theory for randomized stratified design.

Fyke-net Surveys: We use fyke nets to sample 18 sites around the lake representative of nearshore habitat types. Sites were selected to represent the common substrates in the nearshore in the proportions they occur and distributed around both shores of the lake as evenly as possible while still achieving substrate representation. Each site is sampled via approximately 24 hour sets of a fyke net comprised of a $3 \mathrm{ft}(0.9 \mathrm{~m}) \times 5 \mathrm{ft}(1.5 \mathrm{~m})$ frame fitted with $1 / 2$ in ( 12.7 mm ) delta knotless mesh. In 2008, we concurrently sampled 14 sites with a fyke net comprised of a $3 \times 5 \mathrm{ft}$ frame fitted with $1 / 4$ in ( 5 mm ) delta knotless mesh. From 2009 onwards, all 18 sites were sampled with nets of both mesh sizes. Sampling is typically initiated around September 15 of each year.

Seine surveys: Daytime seining with a $75 \mathrm{ft}(23 \mathrm{~m})$ beach seine with $1 / 4 \mathrm{in}(5 \mathrm{~mm})$ mesh is conducted monthly at 9 sites from July through September with noncontinuous long-term data available.

Centrarchid surveys: In spring 2011, we initiated a shoreline electrofishing survey directed at Centrarchid spp. Methodology for spring electrofishing surveys was similar to NYSDEC black bass surveys (Brooking et al. 2018). Sampling is initiated when water temperatures reach $20^{\circ} \mathrm{C}$. Eight sites were selected to both proportionally represent typical shoreline habitats in the lake and achieve spatial coverage of both the north and south shores. Each site is comprised of an initial 15 minute all fish pick up followed by a 1 hour predator sample and concluded with another 15 minute all fish pick up. Spring centrarchid surveys are scheduled to be conducted 2 of every 3 years, with walleye mark-recapture years excluded.

Trap-net surveys: Trap-net surveys were conducted in spring and fall using a net design introduced to Oneida Lake by early settlers (Kingsbury 1964). The net consisted of a 6X6X6 ft crib, outside and inside wings with a combined length of 42 ft , and a first heart with turnaround that led into a second heart with turnaround that funneled into a third heart in the crib. The net utilized a 150 ft lead, and all sections were constructed of 1 in bar mesh multifilament netting. The net was set at the same site off Shackelton Point each season and was typically fished 710 d in April-May and October. The net was tended daily or as weather permitted. Spring trapnet surveys were conducted most years since 1992 and fall trap-net surveys were conducted in four years prior to 1961 and most years since 1980.

Creel surveys: The current approach is to conduct an abbreviated summer survey each year, basing effort on boat counts from a fixed location in May, June and July and basing catch and harvest on exit interviews conducted at three locations during June and July. A complementary full open water roving survey is conducted every fifth year. Methods for the full open water roving survey are provided in Krueger et al. (2009).

For the abbreviated survey, effort is estimated by fixed point boat counts conducted from a tower on the CBFS property. Counts are conducted at two random times on two randomly selected weekdays and both weekend days through the counting season and effort in boathours calculated following the methods described in Krueger et al. (2009). Boat-hours are converted to angler-hours by multiplying boat-hours by the average party size calculated from exit interviews in June and July. Exit interviews are conducted on two randomly selected weekdays and both weekend days during either a morning shift (0800-1400) or afternoon shift (1400-2000), also randomly selected. Exit interviews are conducted at three boat launches, South Shore Boat Launch, Godfrey Point Boat Launch and Oneida Shores, and location for each day is randomly selected. Catch and harvest rates are calculated using the ratio of means following methods described by Krueger et al. (2009).

Harvest rates of walleye from June and July are used to predict a harvest rate for the entire open water season, and this rate is combined with effort estimated for the entire open water season to predict total walleye harvest. Analyses of seasonal patterns in walleye harvest rates estimated during roving creel surveys for the entire open water season indicated a good predictive relationship existed between rates observed in June and July and full open water season rates.

The open water walleye harvest rate was predicted by the relationship:
$H R=0.761(J J H R)+0.012$
where HR is the harvest rate predicted for the entire open water season and JJHR is the mean of June and July harvest rates ( $r^{2}=0.85 ; p=0.003$ ).

Beginning with the 2016 season, we also estimate full open water season effort based on counts from a subset of months. We found that effort estimates from May, June and July predicted total season effort, accounting for $96 \%$ of the variability observed over 11 seasons of full effort data. The relationship was;

OWEFFORT $=31,302.9+(1.2(\mathrm{ME}+\mathrm{JnE}+\mathrm{JuE}))$
where OWEFFORT is effort predicted for the entire open water season and ME, JnE and JuE are May, June and July effort, respectively ( $r^{2}=0.96 ; p<0.0001$ ).

## Appendix 2: Standard Data Tables

Table A1. Physical, chemical and biological characteristics of Oneida Lake since 1975. Secchi depth (ft), chlorophyll a ( $\mu \mathrm{g} / \mathrm{L}$ ), total phosphorous (TP, $\mu \mathrm{g} / \mathrm{L}$ ) soluble reactive phosphorous (SRP, $\mu \mathrm{g} / \mathrm{L}$ ), total zooplankton biomass ( $\mu \mathrm{g} / \mathrm{L}$ ), and Daphnia spp. biomass ( $\mu \mathrm{g} / \mathrm{L}$ ) are averages of weekly data from 1 to 5 stations from May to October. Mussel biomass is lake-wide average shell-on dry weight weighted by substrate in $\mathrm{g} / \mathrm{m}^{2}$. Ice in day (day since Dec 1), ice duration and ice out day (day of year) are noted at CBFS and refer to the year of ice break-up. The lake was not completely frozen over in the winter of 200102. Summer temperature ( ${ }^{\circ} \mathrm{F}$ ) is the average temperature from June to Aug measured every hour at 6 ft depth at a site near Shackelton Point.

| Year | Secchi | Chl-a | SRP | TP | Zoopl. Biomass | Daphnia Biomass | Mussel biomass | First Freeze Day | Ice Duration | $\begin{aligned} & \text { Ice } \\ & \text { Out } \end{aligned}$ Day | Sum Temp |

Table A5. Mean catch per haul in $75 \mathrm{ft}(22.9 \mathrm{~m})$ standard beach seine for Oneida Lake in various years since 1959. Data for the 9 standard sites only. Surveys conducted once per month in July, August and September (some years surveys conducted in 1 or 2 of the months only; months sampled identified by subscript in \# of surveys column). Data provided for the main species of interest (does not include less abundant species).

Table A9. Walleye age-specific density estimates (\#/acre) for Oneida Lake since 1957. Ages 1, 2 and 3 walleyes are estimated from the average of trawl and gill-net estimates using catchabilities in Irwin et al. (2008). Bold values are from mark-recapture estimates. Densities of walleyes for intervening years were approximated from the distribution of mortality between successive population estimates. Estimates from 1978-1987 and 1992-1994 from Irwin et al. (2008).

| Year | Age-1 | Age-2 | Age-3 | Age-4 | Age-5 | Age-6 | Age $\geq 7$ | Total (Age $\geq 4$ ) |

Table A10. Fish observed in stomachs of yearling and older walleye taken by trawls and electrofishing during October and November for Oneida Lake since 1971, expressed as numbers per pound of walleye (ES-emerald shiner; Gizz-gizzard shad; Morone-white perch or white bass; RG-round goby; YP-yellow perch; UID-unidentified).

| Year | \# examined | \% empty | ES | Gizz | Morone | RG | YP | Other | UID | Total |

Table A11. Young of year and age-1 walleye density estimates and mean lengths for Oneida Lake since 1961. Larval walleye density (\#/acre, at the time of the 8 mm perch survey) are from Miller sampler surveys at that time or calculated from the 9 mm larval walleye survey. Age-0 walleye densities (\#/acre) and mean lengths (TL, inches) on October 1 are from trawl surveys surrounding the October 1 date ( 5 dates, 50 trawls), and age-1 walleye densities (\#/acre) and mean lengths on May 1 are from trawl surveys around May 1 (3 dates, 30 trawls). Densities calculated based on area swept assuming no avoidance.

| Year-class | Larval Density | Age-0 Density | Age-0 Length | Age-1 Density | Age-1 Length |

Table A13. Young of year and age-1 yellow perch density (\#/acre) estimates and mean lengths for Oneida Lake since 1961. Larval yellow perch densities (at 18 mm ) are estimated from Miller sampler surveys. Age-0 yellow perch densities, age-0 mean lengths (TL, in) are estimates for October 15 obtained from regression analysis of weekly catches throughout the season. Age-1 yellow perch densities are from trawl surveys around May 1 and from mid-July through October. Age-1 yellow perch mean lengths (TL, in) are from spring trawl surveys centered on May 1 since 1961.

Table A14. Relative abundance of white perch year-classes at successive stages of development for Oneida Lake since 1961. Age-0 white perch abundance represented by the calculated density from area swept in trawls in August-September, Age-0 length is from October trawls, Age-1 spring is from the CPUE in spring trawls, and age-1 and older are catches in standard gill nets. These values are data for the year of collection. The recruitment index ( RI ) is the sum of the gill-net catch at age-2 and 3 of fish born that year (Fitzgerald et al. 2006). For example the RI value for years 1961 is the sum of the gill-net catch of age-2 in 1963 and age-3 in 1964. Bold RI numbers for 1971 and 1972 includes an extrapolation of gill-net catches for 1974 when gill nets were not used (see Fitzgerald et al. 2006).

Table A16. Total annual consumption (tons $=2000 \mathrm{lbs}$ ) by double-crested cormorants and numbers of percids consumed by age-class for Oneida Lake since 1978. Feeding days to 2010 are based on Coleman et al. (2016), which also includes numbers consumed by age class for 1995 - 2010. Consumption estimate assumes a double-crested cormorant consumes 1.0 pound of fish per day.

| Year | Feeding Days | Consum. (Tons) | Walleye |  |  |  | Yellow perch |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
