Cold-blooded in the cold:

hibernation

What's asleep
under the snow
and ice?
In this issue:
we'll learn about some of the animals that hibernate to survive our northern winters. You've probably already read a lot about mammals like bears and bats sleeping through the winter. We're going to focus on the animals we don't hear about as much: insects, reptiles and amphibians. Welcome to "cold-blooded in the cold"!

Want to receive Conservationist for Kids at home?
Subscribe to Conservationist magazine!
You'll get six issues of the award-winning Conservationist magazine each year, plus Conservationist for Kids in the October, February and April issues.
Call 1-800-678-6399 to subscribe.

Send us a photo of yourself enjoying the outdoors.

WHY HIBERNATE?

It takes energy to stay active and warm. Energy comes from food, which is often difficult to find in the winter. Some animals have adapted to survive the cold by going through a long period of dormancy. During this special time, their body functions like heart rate and breathing slow way down. By hibernating, they conserve energy and improve their chances for surviving until warmer weather returns in the spring, along with more plentiful food.

MAMMALS are warm-blooded. When they’re active, their body temperature stays pretty much the same. When mammals hibernate, their body temperature drops, breathing and heartbeat slow down, and they don’t need as much food as when they’re active. Depending upon the species, body fat put on in the late summer and fall may be enough to carry them through the winter, or they may wake periodically for a snack from food they’ve stored in their burrow.

REPTILES and AMPHIBIANS are cold-blooded. Their body temperature goes up and down with the temperature of their surroundings. They will not survive out in the snow and ice. If you know where they hibernate, you’ll know where to start looking for them when spring arrives.

INSECTS can’t be active during the deep freeze, but that doesn’t mean you won’t see them. Depending upon the species, they may spend the winter as eggs, larvae and pupae, and occasionally as adults.
Put on your pajamas, have a little bedtime snack, crawl into bed and pull up the covers.

Nighty-night, see you in the morning!

But what if “bedtime” is fall, and the time to wake is spring?

For animals that hibernate, bedtime preparations are not like yours. The clock doesn’t signal bedtime. Instead, shorter days, colder temperatures and less available food may work together to trigger hibernation.

*That bedtime snack is actually weeks, possibly months, of eating lots of food to put on body fat. The hibernating animal will then rely on this stored fat as food. (Some smaller mammals wake up for short periods during hibernation and eat from food stored in their underground burrows, in addition to using up body fat.)

A Cozy Bed

For frogs and turtles, the mud at the bottom of the pond is a cozy winter spot. It’s even above freezing, since the water temperature may remain around 40 degrees, insulated from the cold air above by a layer of ice.

If the pond bottom isn’t a good option, how about underground? Many mammals, plus snakes, toads, and salamanders, spend the winter underground in rocky crevices, burrows, or under logs and leaves on the forest floor. Bats go underground in caves. If they go far enough underground, animals can get below the “frost line,” below where the ground is frozen and the earth is still soft. Pile a blanket of snow on top for extra cover, and it’s pretty cozy. Tucked away in a cocoon, many insects provide their own blanket.

Pile a blanket of snow on top for extra cover, and it’s pretty cozy. Tucked away in a cocoon, many insects provide their own blanket.
Some INSECTS spend winter as eggs. Others overwinter as larvae, wrapped in a cozy cocoon for the season. And some spend winter as adults.

**Diapause** (die-a-paws) is the name given to the special kind of dormancy insects go through. During diapause growth is put “on hold.” It can begin well before conditions get bad and can last long after conditions have improved. Insects develop glycerol, a sugary alcohol that acts like antifreeze, as winter approaches. This keeps them from freezing to death, even though they’re above the frost line. The glycerol breaks down when the weather warms, and normal growth begins again.

**Where are Tent Caterpillars in winter?**
A close look at trees and shrubs along the forest edge may reveal a hard, shiny, brown material wrapped around the twigs: an egg mass. When spring arrives, watch for tiny caterpillars to hatch out and begin feasting on the buds and leaves. Look especially on black cherry, apple, and sugar maple trees.

**Adult Ladybugs,** also known as ladybird beetles, hibernate under the bark of a tree or in the leaf litter near the tree’s roots. Sometimes they’re even found hibernating in clusters inside people’s homes. Don’t worry. They won’t harm your home and they’ll leave in the spring!

**Woolly Bear Caterpillars,** larvae of the Isabella tiger moth, spend the winter curled up in a sheltered place—under a log, or perhaps under some loose bark. In spring they’ll spin their cocoon and pupate into adult moths.

**Mourning Cloak Butterflies** are sometimes spotted on the first warm days of spring. Why are they out so early? They spent the winter tucked under crevices of bark. When the warm spring sun shines on the bark it warms them, too. They’ll return to their sheltered hideaway before the cold settles in again as the sun goes down.
When air temperature falls, so does the body temperature, heart rate and digestion of these animals. They need to get underground below the frost line, or into a sheltered area where temperatures will not dip below freezing.

**TURTLES**

Instead of breathing with their lungs, as they do during summer, turtles get the oxygen they need by absorbing it through their skin. Sometimes turtles may be seen swimming under the ice. Their bodies will be the temperature of the surrounding water: about 40 degrees F.

Bundled together like a big knot, snakes share body heat—just enough to keep them from freezing.

Snakes, like this garter snake, gather in crevices in rocky places and underground holes. When spring comes, the ground warms. They leave the confined space and begin sunning themselves to warm up.

Look for large numbers of snakes in the spring as they “wake up” and emerge over a few days.

Turtles are usually snuggled into the mud at the bottom of the pond for the winter.
Eating plenty of food through summer and fall will make certain they have enough stored body fat for winter. This body fat will provide all the food they will need until spring when food is plentiful once again.

**FROGS & TOADS**

Most frogs hibernate buried in the mud at the bottom of the pond. Instead of breathing with their lungs, as they would in the summer, they get the oxygen they need by absorbing it through their skin from the surrounding mud. Toads and some frogs hibernate under logs and leaf litter on the forest floor. A blanket of snow will help to keep them warm enough to survive the winter.

**SALAMANDERS**

While aquatic salamanders may be active under the ice through the winter, their land-based cousins are not. Like toads, these salamanders will find shelter and hibernate in underground burrows, under logs and leaf litter on the forest floor, and in rocky crevices.
The Ideas for Exploring Outdoors!

Go on a hunt for a really cool winter insect!

Snow Flea Safari

If the weather is warm, look around the base of trees in forested areas for black specs, like freshly ground pepper. Put your hand near them and they'll leap away. Look closely with your magnifying lens and you'll see six tiny legs, a sure sign that this is an insect. Sometimes there are so many in one area that the snow looks black.

These are adult snow fleas, a type of springtail which overwinters in the leaf litter at the base of trees and emerges on warmer winter days.

Hibernation Highlights

Animals adapt to wintery conditions in variety of ways. Hibernation is a great solution for animals that are unable to migrate, find sufficient food, or regulate their body temperature. Many students are already familiar with hibernation in groundhogs, bats and other mammals, so in this issue of *Conservationist for Kids* (C4K) we have chosen to focus on cold-blooded animals. Information about mammalian hibernation abounds, so only minimal reference is made to it here—simply to help put hibernation in a context students are already familiar with.

Insects, reptiles and amphibians have some fascinating takes on hibernation, sure to excite young minds. From antifreeze to freezing solid, there is great variation. A blanket of snow is also an important factor for the success of hibernating animals to survive extreme cold. Hibernation studies can be extended to include looking at the insulation qualities of snow, as described in this teacher supplement.

MST Curriculum Connections

The activity on The Outside Page of this issue of C4K correlates to the New York State Learning Standards for Math, Science and Technology for fourth grade, as shown below. Connections to other learning standards are also valid.

Supplemental Activities for the Classroom

A Blanket of Snow
If you have at least 12 inches of snow, it can be fascinating to compare the temperature above and below the snow. There are many different ways to demonstrate the insulating quality of snow. Here’s one, with internet links for more ideas.

**Snow Temperature Gradient**—Divide the class into small groups and give each group a thermometer, a yard stick, a shovel, and a page on which to record their data. (A recording sheet is available for downloading at [www.dec.ny.gov/education/40248.html](http://www.dec.ny.gov/education/40248.html).) Have each group go to a different area of the schoolyard or other open space and record the depth of the snow. At each study site, have the students cut straight down into the snow so they can see the profile, and move away some of the snow so they can reach the ground. Have them measure and record the temperature of the snow at different depths, including at ground level and at the surface. Ask them to consider where they’d rather be on a cold, windy day, and why. Compare notes with other groups and see if different snow conditions (icy and compacted vs. light and fluffy) result in different insulation values. (HINT: They do.)

**Frogsicles!**
On page 7 of this issue of C4K, we have a photo of a hibernating wood frog. Close inspection of the image will show ice crystals on the animal. To help your students to better understand this extreme adaptation to winter—freezing solid—it’s worth visiting the web site of Dr. Kenneth Storey at Carleton University in Canada. The process wood frogs go through is described, and numerous photos are on the site. Links are provided to other sites with supporting information. Lessons to demonstrate the process wood frogs go through are available from Scientific American Frontiers (PBS).
